ABSTRACT

The physical origin of Little Red Dots (LRDs)—compact extragalactic sources with red rest-optical continua and broad Balmer lines—remains elusive. The redness of LRDs is likely intrinsic, suggesting optically thick gas emitting at a characteristic effective temperature of ~ 5000 K. Meanwhile, many LRD spectra exhibit a Balmer break, often attributed to absorption by a dense gas shell surrounding an AGN. Using semi-analytical atmosphere models and radiation transport calculations, we show that a **super-Eddington accretion system** can give rise to a Balmer break and a red optical color simultaneously, without invoking external gas absorption for the break or dust reddening. The break originates from a discontinuity in opacity across the Balmer limit, similar to that of early-type stars, but the lower photosphere density of super-Eddington systems, $\rho < 10^{-9}$ g cm⁻³, implies a significant opacity contrast even at a cool photosphere temperature of ~ 5000 K. Furthermore, while accretion in the form of a standard thin disk requires fine tuning to match the optical color of LRDs, an alternative scenario of a **geometrically thick, roughly spherical accretion flow** implies an effective temperature $4000 \text{ K} \lesssim T_{\text{eff}} \lesssim 6000 \text{ K}$ that is very insensitive to the accretion rate (analogous to the Hayashi line in stellar models). The continuum spectra from the latter scenario align with the Balmer break and optical color of currently known LRDs. We discuss predictions of our model and the prospects for more realistic spectra based on super-Eddington accretion simulations.

1. INTRODUCTION

Since its launch, the James Webb Space Telescope (JWST) has revealed a previously unrecognized population: compact sources that exhibit broad emission lines and a distinctive V-shaped continuum, characterized by blue rest-frame ultraviolet (UV) and red rest-frame optical colors (e.g., I. Labbé et al. 2023; I. Labbe et al. 2025; V. Kokorev et al. 2024; J. E. Greene et al. 2024; D. D. Kocevski et al. 2024; J. Matthee et al. 2024a). These objects, now colloquially referred to as “Little Red Dots” (LRDs), have prompted intense investigation as the community seeks to understand their physical nature.

The origin of the redness of LRDs remains an open question. Spectroscopically selected LRDs have rest-

optical colors comparable to blackbodies of $T \sim 4000$ – 5000 K (e.g., see Figure 1 in D. J. Setton et al. 2024, where a 5000 or 4000 K blackbody would have a rest-frame color of $B - R = 1.20$ or 1.86 in their definition). At first, dust attenuation of an AGN, a stellar population, or mixture of both seemed a straightforward candidate explanation, and spectral continuum fits typically infer $A_V > 1$ (e.g., D. D. Kocevski et al. 2023; J. E. Greene et al. 2024). However, the presence of dust is stringently constrained by the nondetection of its thermal emission in the rest-mid- and far-infrared (C. C. Williams et al. 2024; H. B. Akins et al. 2024; I. Labbe et al. 2025; B. Wang et al. 2025; D. J. Setton et al. 2025; C. M. Casey et al. 2025), indicating that the rest-optical continuum emission is likely intrinsically red rather than dust-reddened. In addition, the strikingly high abundance of LRDs at high redshifts (a few percent of the number density of UV-selected galaxies at $z \sim 5$, e.g.,

V. Kokorev et al. 2024; J. Matthee et al. 2024a; J. E. Greene et al. 2024) implies that the optical redness must be produced without fine-tuning.

Another puzzling property of LRDs is the common presence of a Balmer break in their spectra. Even for objects that do not exhibit a strong spectral discontinuity, the turnover points of the V-shaped continuum appear to be consistently located at the Balmer limit (D. J. Setton et al. 2024). The break feature suggests that an evolved stellar population may dominate the observed flux at $\lambda_{\text{rest}} \sim 4000 \text{ \AA}$. However, this picture is not easily reconciled with the luminous Balmer emission lines (B. Wang et al. 2024; Y. Ma et al. 2025), and the central stellar density implied by an evolved stellar population model is rarely seen, if at all, at lower redshifts (e.g., J. F. W. Baggen et al. 2024; I. Labbe et al. 2024; Y. Ma et al. 2025). Moreover, the Balmer breaks of some recently reported objects are too strong to be explained by standard stellar population models (R. P. Naidu et al. 2025; A. de Graaff et al. 2025) and demand a non-stellar origin. A high covering fraction of dense gas, where neutral hydrogen is collisionally excited to the state of principal quantum number $n = 2$, is proposed to produce the break feature without stars (K. Inayoshi & R. Maiolino 2025), and has since been applied to interpret objects showing strong breaks (e.g., X. Ji et al. 2025; R. P. Naidu et al. 2025; A. de Graaff et al. 2025; A. J. Taylor et al. 2025). This scenario provides a phenomenological solution to the Balmer break but lacks a dynamical picture of the inferred dense gas shell. Moreover, these models have limited predictive power for the optical color, which remains sensitive to the assumed incident spectrum and gas conditions.

Independently, increasing attention has been given to the hypothesis that LRDs are powered by super-Eddington accretion onto a central supermassive black hole (F. Pacucci & R. Narayan 2024; E. Lambrides et al. 2024; K. Inayoshi et al. 2024; P. Madau & F. Haardt 2024; A. Trinca et al. 2024). Super-Eddington accretion was proposed in part to reconcile the broad permitted emission lines seen in LRDs with features that differ from typical Type-I AGNs, including the weakness in X-ray emission (M. Yue et al. 2024; T. T. Ananna et al. 2024; R. Maiolino et al. 2025) and the scarcity of UV/optical variability (M. Kokubo & Y. Harikane 2024; Z. Zhang et al. 2025). However, whether super-Eddington accretion can in fact produce the optical redness and the Balmer breaks of LRDs is underexplored. This motivates us to explore simple super-Eddington models in the context of the continuum signatures in JWST observation.

In this work, we construct idealized semi-analytical models for the gas around a supermassive black hole undergoing super-Eddington accretion and investigate the resulting UV/optical continuum emission. Figure 1 sketches the models considered. First, we study a standard, geometrically thin accretion disk, as shown in the left half of the cartoon. Such a thin disk may be present at super-Eddington accretion rates at large radii. This disk must, however, be truncated at an inner radius to reproduce the redness of LRDs. An alternative picture, more consistent with super-Eddington simulations (e.g., K. Ohsuga et al. 2005; Y.-F. Jiang et al. 2014; J. C. McKinney et al. 2014; A. Sadowski et al. 2014; Y.-F. Jiang et al. 2019; H. Hu et al. 2022), is that a combination of inflow and outflow is distributed over a wide range of polar angles. In this initial exploratory work we approximate this with a spherical model, as indicated on the right in Figure 1.

We investigate whether super-Eddington accretion flows with these simple geometries can reproduce the observed properties of LRDs. Using radiation transport simulations, we compute the gas temperature and emergent continuum flux ab initio, capturing the optical color and the Balmer break self-consistently. Our results revolve around two themes. First, if super-Eddington accretion produces a red optical color from a cool photosphere, then a Balmer break is to be expected from this very photosphere. This is true for both the disk and sphere scenarios and stems from the low density of the gas at the photosphere, $< 10^{-9} \text{ g cm}^{-3}$, compared to that of most main-sequence stars. Second, the cool photosphere itself is a natural outcome of the sphere scenario, in which the effective temperature is very insensitive to the accretion rate in the range $4000 \text{ K} \lesssim T_{\text{eff}} \lesssim 6000 \text{ K}$ due to the temperature dependence of the opacity law (see a similar scenario in D. Kido et al. 2025, which we became aware of near the completion of this manuscript).

In the rest of this paper, Section 2 provides the physical grounds for our first theme, where we use a toy model to show that the Balmer break can emerge from a cool, low-density photosphere. We describe in Section 3 our numerical methods common for the disk and sphere models. In Sections 4 and 5, we construct analytical density structures for the disk and sphere scenarios, respectively, and report our simulation results of the emergent continuum spectra. In particular, readers mainly interested in the spectral results may move directly to Section 4.2 and 5.3. We summarize our results, compare this study to previous works, and outline future directions in Section 6. We have made our model continuum spectra of the sphere scenario pub-

Figure 1. Cartoon showing the scenarios considered in this work. Straight or curved arrows indicate direction of gas flow. Dashed lines represent the photosphere. Wiggle arrows indicate photons. *Left:* A standard thin disk in super-Eddington accretion, which we investigate in Section 4. It reproduces the red optical color and Balmer break of LRDs if the disk has an inner truncation radius where the effective temperature is ~ 5000 K, which is fine-tuned. *Right:* A spherical gas profile undergoing turbulent accretion, which we investigate in Section 5. This model gives rise to a red optical continuum and the Balmer break over a large range of gas densities (a proxy for a wide range of accretion rates). Components with question marks are discussed in Section 6.

licly available on GitHub³. Throughout this work, we refer to radiation frequencies and wavelengths in the rest frame unless otherwise noted. We adopt the Planck Collaboration et al. (2016) cosmological parameters, i.e., $\Omega_m = 0.307$, $\Omega_\Lambda = 0.693$, $\Omega_b = 0.0486$, and $H_0 = 67.7 \text{ km s}^{-1} \text{ Mpc}^{-1}$.

2. BALMER BREAK FROM COOL, LOW-DENSITY PHOTOSPHERES

The Balmer break is well studied in the stellar context: it is associated with a discontinuity in opacity in wavelength space. The same radiation microphysics should apply to supermassive black hole accretion flows (e.g., I. Hubeny et al. 2000, who showed that spectral discontinuities could be present in theoretical AGN disk spectra). However, among main-sequence stars, only those with $T_{eff} \sim 10^4$ K show a strong Balmer break, raising the question of how this feature can be reconciled with the cooler optical color temperatures (~ 5000 K) observed in LRDs. In this section, we build a toy model to show that the same opacity law responsible for the Balmer break in early-type stellar atmospheres can also produce this feature in photospheres at $T \sim 5000$ K. This occurs if the photospheric density is sufficiently

low, which can result from super-Eddington accretion flows.

In general, non-blackbody spectral features may arise from an atmosphere with a temperature gradient along the line of sight. Define a frequency-dependent radiation temperature, $T_{rad,\nu}$. It is determined by the gas temperature at the frequency-dependent photosphere, i.e., the location where the monochromatic optical depth, τ_ν , becomes of order unity. If the optical depth strongly varies with frequency, the photosphere locations of two nearby frequencies may differ substantially, which then implies a varying radiation temperature with frequency. In the special case of the Balmer break, the optical depth variation originates from the photoionization opacity as a neutral hydrogen atom with principal quantum number $n = 2$ absorbs a photon of wavelength $\lambda < \lambda_\infty = 3645 \text{ \AA}$ and becomes ionized.

We illustrate the Balmer break using the following toy model. In a 1D spatial coordinate in z , we assume a plane-parallel gas slab of constant density ρ for $z > 0$ and vacuum for $z < 0$. The gas temperature is given by a simple relation $T^4(z) \propto z$, which would be exact in the diffusive energy transport regime satisfying local thermal equilibrium (LTE) with a constant Rosseland mean opacity. The radiation temperature at a given frequency is then equal to the gas temperature at the photosphere location, $z_{ph,\nu}$, given by $\rho \kappa_{eff,\nu} z_{ph,\nu} = 2/3$, where $\kappa_{eff,\nu} \equiv \sqrt{3\kappa_{a,\nu}(\kappa_{a,\nu} + \kappa_{s,\nu})}$ is the effective opacity accounting for the absorption and scattering opacities $\kappa_{a,\nu}$ and $\kappa_{s,\nu}$ (G. B. Rybicki & A. P. Lightman 1979). The photosphere (or more precisely, thermalization surface) defined with the effective opacity characterizes where the radiation becomes thermalized with the gas, and we keep using the term “photosphere” in this sense throughout this paper. For simplicity, we assume that $\kappa_{eff,\nu}$ is constant along the slab even though it would change with temperature in reality.

The above assumptions relate the radiation temperature to the effective opacity: $T_{rad,\nu} \propto z_{ph,\nu}^{1/4} \propto \kappa_{eff,\nu}^{-1/4}$. To characterize the Balmer break, we choose two representative wavelengths at 3600 \AA and 4000 \AA and calculate the effective continuum opacity ratio, $\kappa_{eff}(4000 \text{ \AA})/\kappa_{eff}(3600 \text{ \AA})$, to indicate the strength of the Balmer break. A value of this ratio being significantly less than unity will imply a large excess of T_{rad} at 4000 \AA relative to 3600 \AA and hence a strong break. The details of our opacity calculations are described in Section 3.2.

Figure 2 shows the effective opacity ratio as a function of temperature and density, assuming an ideal gas of metallicity $Z = 0.1 Z_\odot$. Each curve has a significant trough, indicating the photosphere temperature fa-

Figure 2. The ratio of two continuum effective opacities (accounting for absorption and scattering), $\kappa_{\text{eff}}(4000 \text{ \AA})/\kappa_{\text{eff}}(3600 \text{ \AA})$, for different temperature and density. A ratio significantly below one tends to produce a Balmer break. Star symbols mark the parameters corresponding to the star Vega and the Sun. The optimal temperature to produce a Balmer break increases with density.

avorable to producing the Balmer break at a given atmosphere density. From now on, for a given density, we term the temperature corresponding to the minimum of the trough the “optimal temperature” for the Balmer break. A typical early A-type main-sequence star, e.g., Vega, has a photosphere gas density of the order $10^{-9} \text{ g cm}^{-3}$ (L. A. Dreiling & R. A. Bell 1980), where Figure 2 indicates an optimal temperature of $\sim 9000 \text{ K}$. The star has an effective temperature of the same value. This agrees with the observed strong breaks of such stars. In contrast, the Sun does not show a strong Balmer break with a photosphere temperature of $\sim 6000 \text{ K}$ and a density of the order $10^{-7} \text{ g cm}^{-3}$ (H. Holweger & E. A. Mueller 1974). The crucial message from the figure is that the trough shifts to lower temperature as the characteristic atmosphere density decreases; as the density is reduced to $< 10^{-10} \text{ g cm}^{-3}$, even an atmosphere temperature of $\sim 5000 \text{ K}$ will give rise to a low opacity ratio and hence to a Balmer break.

The positive correlation between the density and the optimal temperature for the Balmer break is known for early-type stars (e.g., see Figure 10 in D. Mihalas 1965) and can be understood from thermal equilibrium. The difference in the absorption opacity on either side of the Balmer break is equal to the photoionization opacity of the $n = 2$ hydrogen at $\sim 3600 \text{ \AA}$, $\kappa_{2 \rightarrow \infty}$:

$$\kappa_{2 \rightarrow \infty} = \frac{n_2 \sigma_{2 \rightarrow \infty}}{\rho} = \frac{X \sigma_{2 \rightarrow \infty}}{m_p} \frac{n_2}{n_{\text{H}}}, \quad (1)$$

where n_2 is the number density of neutral hydrogen at $n = 2$, n_{H} is the total hydrogen number density, X is the mass fraction of hydrogen ($X = 0.74$ for solar composition, M. Asplund et al. 2009), m_p is the proton mass, and $\sigma_{2 \rightarrow \infty}$ is the ionization cross-section of the $n = 2$ hydrogen, which depends only on atomic physics. Equation (1) implies that $\kappa_{2 \rightarrow \infty}$ is proportional to the fraction n_2/n_{H} for a given chemical composition. On the one hand, a high temperature tends to populate the $n = 2$ level according to the Boltzmann equation. On the other hand, most of the hydrogen will be ionized if the temperature is too high, as indicated by the Saha equation (assuming a system consisting only of electrons, protons, and neutral hydrogen):

$$\frac{x^2}{1-x} = \left(\frac{2\pi m_e k_B T}{h^2} \right)^{3/2} \frac{e^{-I_0/k_B T}}{n_{\text{H}}}, \quad (2)$$

where x is the degree of ionization, $I_0 = 13.60 \text{ eV}$ is the ionization potential of ground-state hydrogen, and m_e, k_B, h are the electron mass, the Boltzmann constant, and the Planck constant. The fraction n_2/n_{H} will decrease as x approaches unity. Therefore, the optimal temperature is close to the ionization temperature, T_{ion} , at which the left-hand side of Equation (2) becomes of order unity. Equation (2) then suggests that T_{ion} positively correlates with n_{H} . This qualitatively explains the trend in Figure 2.

Another notable feature in Figure 2 is that the minimum effective opacity ratio of each curve is consistently of the order 0.1 even as the optimal temperature changes from $\sim 10000 \text{ K}$ to $\sim 5000 \text{ K}$ across different densities. This result appears counterintuitive, since the fraction n_2/n_{H} and hence $\kappa_{2 \rightarrow \infty}$ steeply increase with temperature as $\exp(-3I_0/4k_B T)$ before ionization occurs. However, near the optimal temperature, we observe that the continuum absorption opacity at $\sim 4000 \text{ \AA}$ is dominated by the photoionization opacity of hydrogen with $n = 3$. The latter similarly increases with temperature as $\exp(-8I_0/9k_B T)$. Therefore, both the numerator and the denominator of the opacity ratio are diminished at lower density and temperature, and their ratio, which is proportional to $\exp(-5I_0/36k_B T)$, is relatively insensitive to temperature. This maintains a strong opacity contrast and makes a Balmer break theoretically plausible at an optimal temperature of $\sim 5000 \text{ K}$.

The atmosphere model in this section is simplistic, but the opacity ratio in Figure 2 only depends on atomic physics and the equation of state. The trend applies to more realistic atmospheres as long as LTE holds. The Balmer break is compatible with a cool, $\sim 5000 \text{ K}$ photosphere if the gas density at the photosphere is sufficiently low. We will show in Sections 4 and 5 that such

a low density is a natural outcome of super-Eddington accretion, which explains the optical redness and the Balmer break of the LRDs simultaneously.

3. NUMERICAL METHODS

Our continuum modeling is divided into three steps and schematically shown in Figure 3. The first step is the analytical construction of a hydrodynamic atmosphere profile. This is derived from either a standard accretion disk or a spherical flow; see Sections 4 and 5 respectively. After this step, we will have obtained the density, temperature, and radiation flux as a function of location. However, our analytical temperature profile is based on the diffusion approximation, which breaks down in the optically thin region. This motivates the second step, the numerical evaluation of the temperature by evolving the radiation and gas thermodynamics simultaneously toward a steady state. The simulations in this step are performed under the gray approximation, i.e., the radiation intensities and opacities are independent of frequency. This sets the stage for the final step, in which we fix all hydrodynamic quantities and conduct multigroup radiation transport simulations to obtain the continuum spectra.

Below, in Section 3.1, we describe the simulation setups in the second and third steps, which we apply to both disk and spherical models. Our radiation calculations require opacity as input, and we outline our opacity calculations in Section 3.2.

3.1. From atmosphere models to the continuum spectra

To obtain the steady-state temperature profile of an atmosphere model, we conduct 1D simulations using the non-relativistic gray radiation transport module in ATHENA++ (J. M. Stone et al. 2020; Y.-F. Jiang 2021). In the disk case, each simulation represents a narrow annulus at different radii of the disk. We use a Cartesian coordinate that spans the vertical direction and 32 fixed discrete angles for the radiation. In the sphere case, each simulation represents a radial profile, and we use a spherical polar coordinate and 32 discrete radiation angles that rotate with respect to the local coordinate direction. In both the sphere and disk cases, we fix the density profile from analytical models and only evolve the temperature and the radiation field. The velocity is set to zero, although a small radial velocity is expected in the spherical flow model (see Equation (8)): we test that including the radial velocity does not significantly change the temperature structure or the spectrum but requires longer time to converge. The temperature profile is initialized with the analytical result. The radiation intensities are initialized using the two-stream approximation such that the local radiation energy density and

flux are equal to aT^4 (a being the radiation density constant) and the analytical flux profile, respectively. In the disk case, we set a reflective inner boundary condition on radiation at the disk midplane and an outgoing outer boundary condition at a height where the density has reached a floor value of 10^{-16} g cm $^{-3}$. In the sphere case, we fix the radiation field at the initial value at the inner boundary, a small radius where the continuum is very optically thick, and use an outgoing boundary condition at a large, optically thin radius. We use root grids of 2048–6144 cells depending on specific runs, with adaptive mesh refinement to resolve locations with large temperature gradients. We terminate the simulation when the relative change of the location where $T = 5000$ K, an approximate proxy of the photosphere location, varies by less than one percent per logarithmic time.

The simulation requires opacities as input to solve the radiation transport equation. Specifically, the scattering opacity κ_s , Rosseland mean opacity κ_r (equivalent to $\kappa_s + \kappa_a$ in Y.-F. Jiang 2021), and Planck mean opacity κ_p are needed. Under the assumption of LTE, these opacities depend only on the local gas density and temperature. We prepare a table of these three opacities as a function of density and temperature beforehand (see Section 3.2), covering $10^{-16.5}$ g cm $^{-3} < \rho < 10^{-7.5}$ g cm $^{-3}$ and 1.5×10^3 K $< T < 3 \times 10^5$ K. During the simulation, the opacities are updated with the temperature evolution by linear interpolation from the table in logarithmic space. In the sphere case, we may encounter regions with density or temperature below the table range, and we simply use the nearest value in the table. Opacities at low density may deviate from LTE, and low-temperature opacities are likely strongly modified by dust. However, such regions only exist far beyond the optical continuum photosphere in the sphere models.

After obtaining the numerical temperature profiles, we conduct multigroup radiation transport simulations using ATHENA++ (Y.-F. Jiang 2022) to calculate the continuum spectrum. This calculation solves the radiation transport equation for multiple wavelength groups and thus predicts a spectrum from the model atmosphere. All hydrodynamic quantities, including the temperature, are fixed. We initialize the intensities to follow the Planck distribution defined by the local temperature with a frequency-integrated flux given by the analytical model. For the wavelength groups, we use a wavelength grid spanning $1250 \text{ \AA} < \lambda < 13000 \text{ \AA}$ and a resolution of 50 \AA in UV and $100\text{--}200 \text{ \AA}$ in optical to near-infrared, except for the region near the Balmer break, $3600 \text{ \AA} < \lambda < 3700 \text{ \AA}$, where we refine the bin

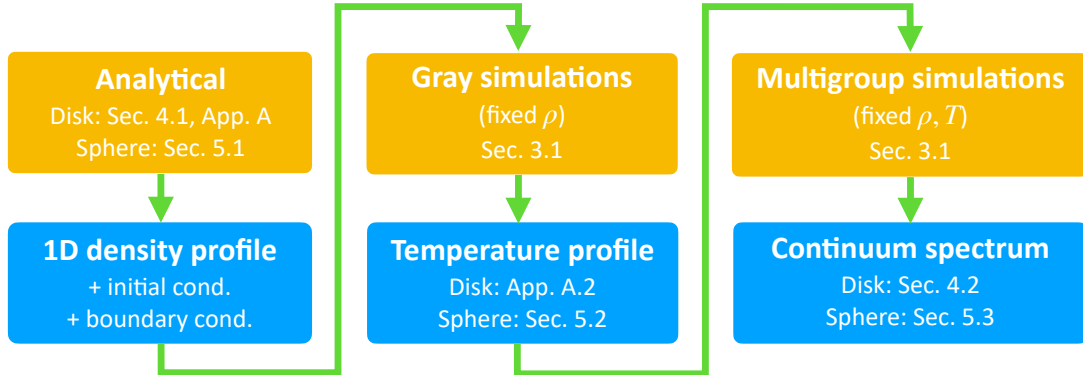

Figure 3. Workflow in this paper. Methods are outlined in yellow blocks, and results are outlined in blue blocks. “Sec.”, “app.”, and “cond.” stand for “section”, “appendix”, and “condition”.

width to 5–10 Å. The total number of wavelength bins is 122. The boundary conditions are the same as the gray simulations. We switch from adaptive to static mesh refinement as the temperature is now fixed. We prepare opacity tables for each wavelength group (see Section 3.2) and initialize the opacities by linear interpolation (and nearest-neighbor extrapolation if needed), similar to the gray simulations. No update in opacity during the simulation is needed here because the gas density and temperature are fixed. We terminate the simulations when the fluxes at all locations and groups vary by less than one percent or less than ten times the machine precision limit per logarithmic time. The fluxes in the z direction in the disk case or in the r direction in the sphere case at the outer boundary constitute the desired spectrum.

3.2. Opacity

Wavelength-dependent opacities as a function of density and temperature are extensively used in this work. To prepare the opacity table, we use the code FASTCHEM (Version 2, J. W. Stock et al. 2022) to evaluate the thermochemical equilibrium composition of an ideal gas of a given temperature, density, and elemental abundance. We assume a metallicity of $Z = 0.1 Z_{\odot}$ and adopt the M. Asplund et al. (2009) solar composition, although the metallicities of LRDs are very uncertain. The chemical information is then passed to OPTAB (S. Hirose et al. 2022), a public code to generate gas-phase Rosseland and Planck mean opacity tables given the density, temperature and chemical composition. The original code only generates averaged opacities throughout the spectrum, but a slight adaptation allows us to calculate opacities averaged over arbitrary wavelength bins. OPTAB is designed to work with FASTCHEM. Opacity sources implemented in OPTAB include bremsstrahlung (P. A. M. van Hoof et al. 2014; T. L. John 1988, 1975), photoionization (D. A. Verner

& D. G. Yakovlev 1995; D. A. Verner et al. 1996; M. Yan et al. 2001; T. Ohmura & H. Ohmura 1960), scattering (H.-W. Lee 2005; R. D. Rohrmann 2018; S. P. Tarafdar & M. S. Vardya 1973), atomic line absorption (R. L. Kurucz 2019), and molecular line and collision-induced absorption (see their Table 1 and Figure 1). However, in this work, we exclude molecular line absorption and collision-induced absorption, although molecules are accounted for when calculating the chemical composition. The optical effective temperature of most LRDs, ~ 5000 K, is expected to be sufficiently high to suppress the molecular population near the photosphere; moreover, spectrally confirmed LRDs do not seem to exhibit the strong molecular absorption features commonly seen in M-type stars.

Now, we summarize the three use cases of opacities in this work. The first is the effective opacities $\kappa_{\text{eff}}(3600 \text{ \AA})$ and $\kappa_{\text{eff}}(4000 \text{ \AA})$ showed in Figure 2 and $\kappa_{\text{eff}}(5000 \text{ \AA})$ used in Figures 5 and 6. They are obtained as the Planck mean of the quantity $\sqrt{3\kappa_{a,\nu}(\kappa_{a,\nu} + \kappa_{s,\nu})}$ over the wavelength ranges $3600 \text{ \AA} \leq \lambda \leq 3620 \text{ \AA}$, $4000 \text{ \AA} \leq \lambda \leq 4020 \text{ \AA}$, and $5000 \text{ \AA} \leq \lambda \leq 5020 \text{ \AA}$ respectively. We use these opacities to diagnose the continuum, and thus only the continuum opacity sources are included. The second is the Rosseland and Planck mean opacity tables for our analytical calculations and gray simulations. These opacities include the line contributions; we also tested excluding them and found similar temperature structures in the gray simulations. The third is the multigroup opacities for spectral calculations. We only include the continuum opacity sources here because of our primary interest in the continuum and because of the computational cost of resolving individual lines, which is necessary for multigroup calculations to achieve spectral accuracy. With insufficient resolution, the line opacity would be smeared out to the entire wavelength bin that contained the line and appear as an unphysically enhanced continuum opacity. We

caution that our treatment neglects metal line blocking. This effect tends to redden the continuum, although the extent depends on metallicity. Balmer lines also modify the spectrum on the red side of the Balmer limit, and thus realistic spectra would have a smoother increase in the range $3645 \text{ \AA} < \lambda \lesssim 4000 \text{ \AA}$ than our calculations, especially in the presence of Doppler broadening. However, the strength of the Balmer break depends only on hydrogen photoionization, which is fully considered in our multigroup opacity calculations.

4. THE DISK SCENARIO

In this section, we consider the structure and continuum spectrum of a standard thin disk in the context of LRDs. The standard disk in the sub-Eddington regime has been found to produce a Balmer break if relatively cool annuli at $T_{\text{eff}} \lesssim 10^4 \text{ K}$ dominate the emission spectrum (I. Hubeny et al. 2000, although they cautioned about uncertainties in the disk vertical structure). Bright UV continuum emission is theoretically expected to hide the break, which is consistent with the lack of a Balmer break in the spectrum of typical Type-I AGNs. However, LRDs are fainter in the UV and likely require cool emission components to dominate the optical continuum. This motivates us to revisit the thin-disk model and explore the parameter range that may reproduce the Balmer break and the optical redness of the LRDs.

In the remainder of this section, we follow the workflow outlined in Figure 3. Section 4.1 examines basic properties of the disk using a vertically integrated model, which constrains the parameter space relevant to LRDs and suggests a low- T_{eff} Balmer break at high accretion rates. We then evaluate the vertical density and temperature structures of the disk with analytical calculations and gray simulations, with details provided in Appendix A. Finally, in Section 4.2, we present the continuum spectra from multigroup simulations, which support the presence of a low- T_{eff} Balmer break but also highlight a fine-tuning problem inherent to the disk model.

4.1. Analytical considerations

We consider the standard model of a geometrically thin, optically thick, non-self-gravitating accretion disk around a black hole of mass M_{BH} and mass accretion rate \dot{M} . Assuming that the angular velocity at a given disk radius r is Keplerian, the effective temperature,

$$T_{\text{eff}} = \left(\frac{3GM_{\text{BH}}\dot{M}}{8\pi\sigma r^3} \right)^{1/4}, \quad (3)$$

is only a function of M_{BH} , \dot{M} , and r . Here, G and σ are the gravitational constant and the Stefan-Boltzmann

constant. We have ignored a factor $(1 - \sqrt{R_{\text{ISCO}}/r})$ in the bracket in Equation (3), where R_{ISCO} is the innermost stable circular orbit and has a value of several gravitational radii, $R_{\text{g}} \equiv GM_{\text{BH}}/c^2$. This is because we are interested in the cool, outer disk, where $r \gg R_{\text{ISCO}}$.

The fixed power-law $T_{\text{eff}} \propto r^{-3/4}$ implies that the disk continuum spectrum has three regimes. Let R_{in} and R_{out} ($R_{\text{ISCO}} \ll R_{\text{in}} < R_{\text{out}}$) denote the disk's inner and outer truncation radii. For $\lambda < hc/k_B T_{\text{eff}}(R_{\text{in}})$, the continuum is dominated by emission from the innermost annulus. In the intermediate range, $hc/k_B T_{\text{eff}}(R_{\text{in}}) < \lambda < hc/k_B T_{\text{eff}}(R_{\text{out}})$, assuming blackbody emission, the spectrum follows $L_\lambda \propto \lambda^{-7/3}$. For $\lambda > hc/k_B T_{\text{eff}}(R_{\text{out}})$, the Rayleigh-Jeans tail dominates, with $L_\lambda \propto \lambda^{-4}$. The latter two regimes are too blue to match the optical continuum of LRDs, leaving only the innermost annulus as a plausible source. Reproducing the observed optical color temperature of $\sim 5000 \text{ K}$ thus requires $T_{\text{eff}}(R_{\text{in}}) \sim 5000 \text{ K}$. As we shall see, such models face a significant fine-tuning issue, in that emission from disk annuli hotter than $\sim 5000 \text{ K}$ needs to be excluded for the disk model to reproduce LRD spectra; there is, to our knowledge, no generic reason why such a truncation of the disk should occur at this particular effective temperature.

Notwithstanding this challenge, if we assume that the optical continuum of LRDs does emerge from a standard disk truncated at $T_{\text{eff,in}} \equiv T_{\text{eff}}(R_{\text{in}}) \sim 5000 \text{ K}$, then the total (one-sided) disk luminosity will be given by

$$L_{\text{disk}} \simeq \frac{3GM_{\text{BH}}\dot{M}}{4R_{\text{in}}} = 8.4 \times 10^{43} \text{ erg s}^{-1} \left(\frac{T_{\text{eff,in}}}{5000 \text{ K}} \right)^{4/3} \times \left(\frac{\lambda_{\text{Edd}}}{10^2} \right)^{2/3} \left(\frac{M_{\text{BH}}}{10^7 M_\odot} \right)^{4/3}. \quad (4)$$

Here, we recast the accretion rate in terms of the Eddington ratio, $\lambda_{\text{Edd}} \equiv \dot{M}/\dot{M}_{\text{Edd}}$, where the Eddington accretion rate is $\dot{M}_{\text{Edd}} \equiv L_{\text{Edd}}/0.1c^2 = 4\pi GM_{\text{BH}}/0.1c\kappa_{\text{es}}$, assuming a conventional mass-to-radiation conversion efficiency of 0.1. We adopt the value of the Thomson electron scattering opacity $\kappa_{\text{es}} = 0.34 \text{ cm}^2 \text{ g}^{-1}$. Currently known LRDs typically have optical continuum luminosities $L_{\text{opt}} \sim 10^{43} - 10^{45} \text{ erg s}^{-1}$ (without dust correction; e.g., see the observed spectra in Figure 4). Equation (4) then suggests that a super-Eddington thin accretion disk can match the LRD luminosities with a black hole mass of $M_{\text{BH}} \sim 10^7 M_\odot$. Note that although the disks we consider are super-Eddington, the annuli $r \sim R_{\text{in}}$ that produce the $T_{\text{eff}} \sim 5000 \text{ K}$ emission will remain consistent with a thin disk with negligible radial advection of energy as long as $R_{\text{in}}/R_{\text{g}} \gg \lambda_{\text{Edd}}$.

The super-Eddington accretion disk is vertically supported by radiation pressure in our region of interest (N. I. Shakura & R. A. Sunyaev 1973). Standard estimates of radiation-dominated accretion disks predict that the central density of the disk is given by

$$\begin{aligned} \rho_c &= 2 \left(\frac{2}{3}\right)^{7/2} \left(\frac{0.1c^3}{\kappa_{\text{es}}G}\right)^{3/2} \alpha^{-1} (\sigma T_{\text{eff}}^4)^{-1/2} (\lambda_{\text{Edd}} M_{\text{BH}})^{-3/2} \\ &= 1.2 \times 10^{-11} \text{ g cm}^{-3} \\ &\quad \times \left(\frac{\alpha}{0.1}\right)^{-1} \left(\frac{T_{\text{eff}}}{5000 \text{ K}}\right)^{-2} \left(\frac{\lambda_{\text{Edd}} M_{\text{BH}}}{10^9 M_{\odot}}\right)^{-3/2}, \end{aligned} \quad (5)$$

where we have expressed the density as a function of effective temperature rather than disk radius, and α is the standard viscous parameter. We have assumed that κ_{es} is the dominant opacity in the disk interior, which is consistent with the disk density we have obtained.

Therefore, the midplane density at high accretion rates goes below the typical density of a main-sequence stellar atmosphere (see Figure 2). We note that the radiation-dominated disk is unstable (A. P. Lightman & D. M. Eardley 1974; Y.-F. Jiang et al. 2013) and that models with magnetic support, which appear stable, have even lower central densities (Y.-F. Jiang et al. 2025). The photosphere density of the disk is expected to be still lower than the midplane density. Our argument in Section 2 then implies a Balmer break when $T_{\text{eff,in}} \sim 5000 \text{ K}$, as we will show with numerical continuum spectra in the next subsection.

4.2. Numerical continuum spectra

Based on the estimates above, we calculate the vertical density and temperature profiles at each radius of the disk, elaborated in Appendix A. We then use these profiles to calculate continuum spectra, which we present in this subsection.

We explore two cases in the disk model. The first case represents a disk around a black hole of mass $M_{\text{BH}} = 10^7 M_{\odot}$ and Eddington ratio $\lambda_{\text{Edd}} = 10^2$. The second case has the same black hole mass but a lower accretion rate, $\lambda_{\text{Edd}} = 1$. The main difference between the two cases is that a lower Eddington ratio corresponds to higher gas densities given the same effective temperature. For example, in the annulus where $T_{\text{eff}} = 5000 \text{ K}$, the photosphere densities of our vertical models (measured at the height where $T = T_{\text{eff}}$) are $1.1 \times 10^{-11} \text{ g cm}^{-3}$ in the first case and $9.4 \times 10^{-10} \text{ g cm}^{-3}$ in the second case. We will show that the difference in density results in the Balmer break emerging at different effective temperatures.

The results for the $M_{\text{BH}} = 10^7 M_{\odot}$, $\lambda_{\text{Edd}} = 10^2$ case are shown in the left panel of Figure 4. To account for

the multiple annuli contributing to the emergent flux, we add the flux from each annulus at radius r multiplied by the surface area $2\pi r^2 \Delta \ln r$, where $\Delta \ln r = 0.1 \ln 10$. The summation is performed from an outer radius where the disk is very cool ($R_{\text{out}} = 10^{4.3} R_{\text{g}}$, corresponding to $T_{\text{eff}} = 3640 \text{ K}$) to an inner radius indicated in the legend: for example, the spectrum marked with $R_{\text{in}} = 10^{4.1} R_{\text{g}}$ is the sum of the luminosities of three annuli at $r = 10^{4.3}, 10^{4.2}, 10^{4.1} R_{\text{g}}$. For reference, we also mark in the legend the effective temperature of each innermost annulus, $T_{\text{eff,in}}$, calculated from Equation (3). The model curves show a prominent Balmer break at 3645 \AA when $R_{\text{in}} \leq 10^{4.1} R_{\text{g}}$. Note that the annulus at $10^{4.1} R_{\text{g}}$ has $T_{\text{eff}} = 5136 \text{ K}$, and the disk spectrum with $R_{\text{in}} = 10^{4.1} R_{\text{g}}$ appears slightly redder than a blackbody at 5000 K in the optical spectrum due to the contribution of the cooler annuli. This illustrates the ability of a super-Eddington thin accretion disk to produce a Balmer break while having a red optical color, as we argued in Section 2. As the truncation radius decreases and hotter annuli are included, the optical continuum becomes bluer, and the flux contrast at the Balmer break is diminished. The effective temperature at $10^{3.8} R_{\text{g}}$ is 8603 K , lower than that of a typical A-type main-sequence star, but the Balmer break is already weakened, as expected from Figure 2 for low-density photospheres.

We also plot in Figure 4 a collection of JWST spectra of LRDs from the literature to represent the range of luminosities and spectral shapes from spectroscopically confirmed sources. The collection consists of all samples in D. J. Setton et al. (2024) that have a V-shaped continuum with significance above 2σ . We highlight among them one source, RUBIES-UDS-31747, whose spectrum was taken as part of the RUBIES program (A. de Graff et al. 2024). The spectrum has an optical continuum luminosity on the order of $3 \times 10^{43} \text{ erg s}^{-1}$, typical among the LRD samples plotted in the background, and visually shows a Balmer break. The model curve with $R_{\text{in}} = 10^{4.1} R_{\text{g}}$ gives an optical red color and a balmer break strength similar to the data. The optical luminosity differs by a factor of two, but a slightly higher black hole mass and Eddington ratio will match observation. Our intention here is not to fit the spectrum but to show the general behavior of disk spectra for parameters relevant to LRDs.

To compare with the high-Eddington ratio case analyzed above, we show in the right panel of Figure 4 the spectra of the $M_{\text{BH}} = 10^7 M_{\odot}$, $\lambda_{\text{Edd}} = 10^0$ case. The outer radius here is $R_{\text{out}} = 10^{3.6} R_{\text{g}}$, corresponding to $T_{\text{eff}} = 3835 \text{ K}$. Similarly to the previous case, different truncation radii result in a range of optical colors. How-

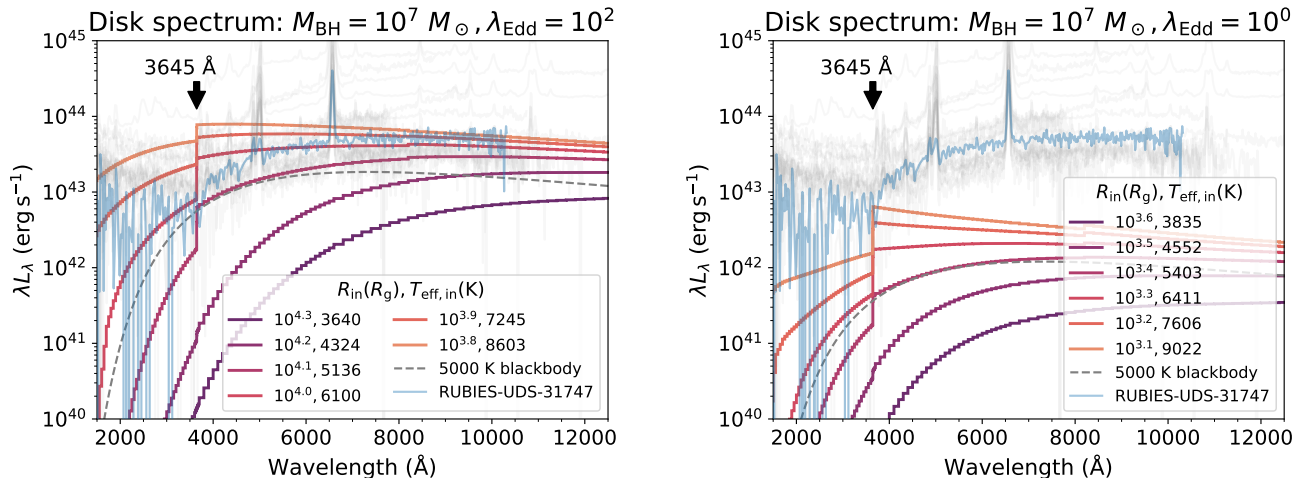

Figure 4. Model continuum spectra in the disk scenario. *Left:* the $M_{\text{BH}} = 10^7 M_{\odot}, \lambda_{\text{Edd}} = 10^2$ case. Each curve shows the flux integrated over disk annuli from R_{in} to $R_{\text{out}} = 10^{4.3} R_g$. The legend marks the inner radius, R_{in} , and the effective temperature at the inner radius, $T_{\text{eff,in}}$, derived from Equation (3). A blackbody curve at $T = 5000$ K and the spectrum of an LRD, RUBIES-UDS-31747, are shown for comparison. A collection of observed LRD spectra are shown in gray in the background. *Right:* Same as left, but for the $M_{\text{BH}} = 10^7 M_{\odot}, \lambda_{\text{Edd}} = 10^0$ case, with $R_{\text{out}} = 10^{3.6} R_g$.

ever, the disk here will become too blue before reaching the optical luminosity of typical LRDs. The optical portion of the model spectrum with $R_{\text{in}} = 10^{3.4} R_g$ has a similar color to that of RUBIES-UDS-31747 but is 30 times dimmer. If we fix R_{in} at $T_{\text{eff}} = 5000$ K, which in both panels produces an optical color similar to LRDs, then Equation (3) suggests $R_{\text{in}} \propto (\lambda_{\text{Edd}} M_{\text{BH}}^2)^{1/3}$, and thus $L_{\text{disk}} \sim 3GM_{\text{BH}}\dot{M}/4R_{\text{in}} \propto (\lambda_{\text{Edd}} M_{\text{BH}}^2)^{2/3}$. This explains the low luminosity in the low- λ_{Edd} case.

The $M_{\text{BH}} = 10^7 M_{\odot}, \lambda_{\text{Edd}} = 10^0$ case is clearly disfavored. However, it helps to illustrate how the Balmer break is related to the disk photosphere condition. At an optical color comparable to that of a $T_{\text{eff}} = 5000$ K blackbody, the case with $\lambda_{\text{Edd}} = 10^0$ shows a weaker Balmer break than the high- λ_{Edd} counterpart (compare $R_{\text{in}} = 10^{3.4} R_g$ on the right to $R_{\text{in}} = 10^{4.1} R_g$ on the left). Moreover, in contrast to the $\lambda_{\text{Edd}} = 10^2$ case, the Balmer break here progressively strengthens when hotter and hotter annuli are included until the innermost annulus reaches $T_{\text{eff,in}} = 9022$ K. Therefore, the Balmer break is optimally produced at a high effective temperature for a low Eddington ratio. We expect this behavior because the Eddington ratio anticorrelates with the photosphere density, which correlates with the optimal temperature, as shown in Figure 2. This supports the connection between the theoretical opacity law in Section 2 and the observable Balmer break feature.

In summary, a truncated super-Eddington disk with a maximum effective temperature of $T_{\text{eff}} \sim 5000$ K produces a Balmer break, optical color, and optical luminosity similar to those of LRDs. The Balmer break and the cool effective temperature are reconciled at the low-

density photosphere. Nevertheless, the model curves in either panel of Figure 4 only span a factor of 3 in R_{in} , but the spread in the optical color already exceeds that indicated by the collection of observed LRDs in the background. The abundance of these objects at similar optical colors requires a model insensitive to free parameters such as the truncation radius, which lies beyond the standard thin disk.

5. THE SPHERE SCENARIO

We have seen that the disk model faces a fine-tuning challenge despite reproducing the observed Balmer break and the optical color of LRDs. Now, we consider an alternative scenario where the gas around the black hole follows a spherical geometry, as sketched in Figure 1. The broad motivation for this is that in super-Eddington accretion, the geometrical thickness of the flow approaches $H \sim r$, with optically thick inflows and/or outflows covering almost all of the solid angle (e.g., K. Ohsuga et al. 2005; Y.-F. Jiang et al. 2014; J. C. McKinney et al. 2014; A. Sadowski et al. 2014; Y.-F. Jiang et al. 2019; H. Hu et al. 2022). In this initial exploratory calculation, we choose to approximate the true, more complicated geometry of such flows with a simple spherical model.

In this section, we construct spherical models and present their simulated spectra, following the workflow in Figure 3. In Section 5.1, we analytically evaluate the photosphere temperature and density, showing that the sphere scenario robustly yields a cool effective temperature. Section 5.2 presents temperature profiles from gray simulations. Finally, in Section 5.3, we report our

model continuum spectra and demonstrate their consistency with the observed optical colors and Balmer break features of LRDs.

5.1. Estimating photosphere properties

We assume that a black hole of mass M_{BH} is surrounded by a steady, spherically symmetric, optically thick flow, with density ρ , inward radial velocity v , and temperature T as a function of radius r . The black hole accretes gas at a rate, $\dot{M} = 4\pi r^2 \rho v$, independent of radius (this assumption is not critical, as we discuss below). We choose to specify the luminosity of the flow L independent of \dot{M} . In super-Eddington accretion, the luminosity is limited to L_{Edd} for a purely spherical laminar inflow but can exceed this limit with more realistic geometries. Our simple model is agnostic to the exact radiative efficiency in that we vary L and \dot{M} independently. The luminosity relates the photosphere radius R_{ph} to the effective temperature T_{eff} by

$$4\pi R_{\text{ph}}^2 \sigma T_{\text{eff}}^4 = L. \quad (6)$$

In the analytical estimate in this section, we assume that the effective temperature is equal to the gas temperature at the photosphere (strictly speaking, the thermalization surface). We consider two estimates of the photosphere location. The conventional choice is to use the Rosseland mean opacity, κ_R , which captures the opacity over the full spectrum. However, when scattering dominates the Rosseland mean opacity (which is the case in our parameter space), the effective temperature calculated in this way may not accurately represent the spectral properties because the spectrum is set deeper in the atmosphere where the photons and gas can thermalize. To account for this, we use the monochromatic effective opacity at 5000 Å, $\kappa_{\text{eff}}(5000 \text{ Å})$, similar to Section 2. The photosphere thus defined denotes the location where optical photons are thermalized and will better reflect the spectral color at $\sim 5000 \text{ Å}$. The “effective temperature” in this case is more properly understood as the color temperature at optical wavelengths, but for simplicity we will continue to refer to it as the effective temperature. We explore both definitions:

$$\rho_{\text{ph}} \kappa(\rho_{\text{ph}}, T_{\text{eff}}) H_{\text{ph}} = \frac{2}{3}, \quad (7)$$

where κ is either κ_R or $\kappa_{\text{eff}}(5000 \text{ Å})$, $\rho_{\text{ph}} = \rho(R_{\text{ph}})$ is the gas density at the photosphere, and H_{ph} is the “photosphere scale height”, or the radius range where the optical depth is of order unity. This height (which we will clarify further in Section 5.2) will be determined self-consistently once we obtain the temperature profile in the numerical calculations, but we treat $H_{\text{ph}}/R_{\text{ph}}$ as

a free parameter in this subsection. Then, the photosphere conditions will be determined if the photosphere density is known.

The photosphere density, or more generally the entire density profile, is related to \dot{M} and v . We assume that the inflow velocity at a given radius is a fixed fraction of the Keplerian velocity:

$$v = \delta \sqrt{\frac{GM_{\text{BH}}}{r}}. \quad (8)$$

Note that this velocity only reflects the net flow, but turbulent gas motion could be faster in principle. In addition, if there is an escaping outflow with a mass outflow rate comparable to \dot{M} , it could have a significantly higher velocity (e.g., N. I. Shakura & R. A. Sunyaev 1973; we will return to this in Section 6). From Equation (8), for a given system, the density profile will follow a power law, $\rho = \dot{M}/4\pi r^2 v \propto r^{-3/2}$. To set a normalization value of this profile, we introduce a free parameter, ρ_{ref} , a reference density at a fixed radius, $R_{\text{ref}} \equiv 1.477 \times 10^{16} \text{ cm}$, which is equal to $10^5 R_g$ for a black hole mass of $10^6 M_{\odot}$. Then,

$$\rho_{\text{ph}} R_{\text{ph}}^{3/2} = \rho_{\text{ref}} R_{\text{ref}}^{3/2}. \quad (9)$$

The reference radius is chosen to be comparable to the photosphere radius given a cool effective temperature. In comparison, if $T_{\text{eff}} = 5000 \text{ K}$, then Equation (6) gives $R_{\text{ph}} = 5.75 \times 10^{15} \text{ cm}$ for $L = L_{\text{Edd}}(10^5 M_{\odot})$, $R_{\text{ph}} = 1.82 \times 10^{16} \text{ cm}$ for $L = L_{\text{Edd}}(10^6 M_{\odot})$, and $R_{\text{ph}} = 5.75 \times 10^{16} \text{ cm}$ for $L = L_{\text{Edd}}(10^7 M_{\odot})$. The reference density thus resembles the midplane density in the disk model in the sense of indicating the order of magnitude of the photosphere density.

The reference density is related to the Eddington ratio as

$$\begin{aligned} \lambda_{\text{Edd}} &= \frac{4\pi r^2 \rho v}{\dot{M}_{\text{Edd}}} \\ &= 1.59 \times 10^3 \frac{\delta}{10^{-2}} \left(\frac{M_{\text{BH}}}{10^6 M_{\odot}} \right)^{-1/2} \frac{\rho_{\text{ref}}}{10^{-12} \text{ g cm}^{-3}}. \end{aligned} \quad (10)$$

Here, δ depends on the turbulent viscosity operating in the sphere and is uncertain. The fiducial value of $\delta = 10^{-2}$ is consistent with an α -disk model with $\alpha = 0.1$ due to the magnetorotational instability (S. A. Balbus & J. F. Hawley 1991) and a dimensionless scale height of ~ 0.3 . Note that the Eddington ratio does not directly appear in our spherical models: the free parameters are L and ρ_{ref} , and Equation (10) only serves to provide some intuition on how to translate ρ_{ref} to λ_{Edd} . We also note that we have assumed a net mass accretion

rate independent of radius, although outflows can significantly reduce the angle-averaged net accretion rate close to the black hole (e.g., Y.-F. Jiang et al. 2019; H. Hu et al. 2022). Thus, the Eddington ratio in Equation (10) should be interpreted as the mass inflow rate at a relatively large distance, with the net accretion rate onto the black hole being possibly significantly lower. A varying net accretion rate with radius would also modify the power law of the density profile in the accretion flow. However, we expect details of the density-radius relation to have a small effect on the emergent flux compared to the photosphere temperature and density because the sphere interior is hidden in the optically thick region.

We also calculate the minimum mass needed to sustain such a photosphere,

$$M_{\text{sph, min}} = \frac{8\pi}{3} \rho_{\text{ph}} R_{\text{ph}}^3 = 2.5 \times 10^4 M_{\odot} \times \frac{\rho_{\text{ph}}}{10^{-12} \text{ g cm}^{-3}} \left(\frac{L}{L_{\text{Edd}}(10^6 M_{\odot})} \right)^{3/2} \left(\frac{T_{\text{eff}}}{5000 \text{ K}} \right)^{-6}. \quad (11)$$

This mass is small compared to the black hole mass ($M_{\text{BH}} \sim 10^5 - 10^7 M_{\odot}$ if we assume $L = L_{\text{Edd}}$). How to fuel this sphere from larger scales is an interesting question but lies beyond the scope of this paper.

We now solve for T_{eff} from Equations (6)(7)(9). Figure 5 shows the effective temperature for $L = L_{\text{Edd}}(10^6 M_{\odot}) = 1.47 \times 10^{44} \text{ erg s}^{-1}$. We first discuss the effective temperature calculated with $\kappa_{\text{eff}}(5000 \text{ \AA})$ (solid curves). For a given $H_{\text{ph}}/R_{\text{ph}}$, the effective temperature decreases with the reference density because a denser sphere tends to increase the optical depth and move the photosphere further out. However, T_{eff} is very insensitive to ρ_{ref} in the range $4000 \text{ K} \lesssim T_{\text{eff}} \lesssim 6000 \text{ K}$. This implies that a wide range of accretion rates tend to produce very similar T_{eff} . For example, if we set $\delta = 0.01$ and $M_{\text{BH}} = 10^6 M_{\odot}$ in Equation (10), then $\rho_{\text{ref}} = 6.3 \times 10^{-16} \lambda_{\text{Edd}} \text{ g cm}^{-3}$. Thus, on the curve of $H_{\text{ph}}/R_{\text{ph}} = 10^0$, a relatively small Eddington ratio of $\lambda_{\text{Edd}} = 10$ will result in $T_{\text{eff}} = 5500 \text{ K}$, while increasing the Eddington ratio by two orders of magnitude only shifts the effective temperature by a small amount, to $T_{\text{eff}} = 4300 \text{ K}$. Our argument has assumed a fixed luminosity, and if the luminosity increases with the accretion rate (and hence ρ_{ref}), as found in many super-Eddington accretion simulations (K. Ohsuga et al. 2005; Y.-F. Jiang et al. 2014; A. Sadowski et al. 2015; Y.-F. Jiang et al. 2019), this would make the effective temperature an even weaker function of ρ_{ref} than the curves in Figure 5. The effective temperature calculated with κ_R (dotted curves) shows similar trends, with an even flatter $T_{\text{eff}} - \rho_{\text{ref}}$ relation at $4000 \text{ K} \lesssim T_{\text{eff}} \lesssim 6000 \text{ K}$, al-

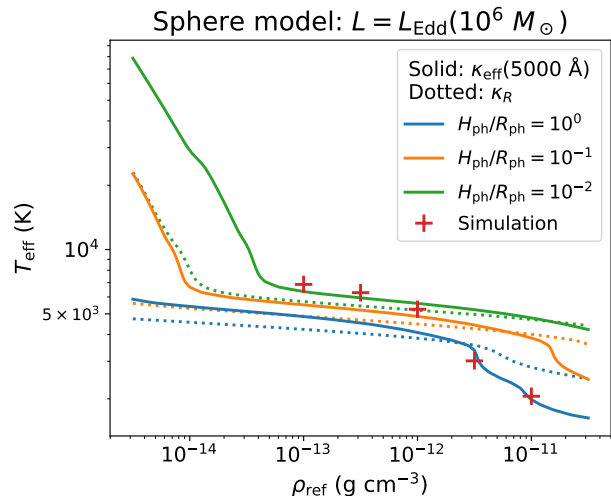

Figure 5. Effective temperature of the sphere model with $L = L_{\text{Edd}}(10^6 M_{\odot})$. The horizontal axis is the reference density, ρ_{ref} , a proxy for the Eddington ratio (Equation (10)) and the photosphere density ($\rho_{\text{ref}} \sim \rho_{\text{ph}}$ if $T_{\text{eff}} \sim 5000 \text{ K}$). Curves show analytical estimates using the effective opacity at 5000 \AA (solid) or the Rosseland mean opacity (dotted). These estimates depend on the dimensionless photosphere scale height, $H_{\text{ph}}/R_{\text{ph}}$, as a free parameter. Plus signs mark measurements of the gas temperature at $\tau_{\text{eff}}(5000 \text{ \AA}) = 1/2$ from the gray simulations, where the photosphere scale height is determined self-consistently by radiation energy transport. The analytical effective temperature is very insensitive to the reference density for a given luminosity and $H_{\text{ph}}/R_{\text{ph}}$, although numerical measurements suggest a somewhat steeper $T_{\text{eff}} - \rho_{\text{ref}}$ relation.

though we again caution that the effective temperature here does not accurately predict optical colors. We will focus on the solid curves hereafter.

The behavior in Figure 5 is due to the sharp increase of opacity with temperature at $T_{\text{eff}} \sim 5000 \text{ K}$. If we parameterize the opacity as $\kappa_{\text{eff}} \propto \rho_{\text{ph}}^{\alpha} T_{\text{eff}}^{\beta}$, then, from Equations (6)(7)(9), $T_{\text{eff}} \propto \rho_{\text{ref}}^{-\frac{(\alpha+1)}{(3\alpha+\beta+1)}}$. At $T_{\text{eff}} \gtrsim 10^4 \text{ K}$, the opacity weakly depends on the density and temperature. We empirically obtain $\alpha \simeq 0.5$, $\beta \simeq -0.6$ from the opacity table, and thus $T_{\text{eff}} \propto \rho_{\text{ref}}^{-0.8}$, in agreement with the leftmost section of the curves with $H_{\text{ph}}/R_{\text{ph}} = 10^{-1}$ and $H_{\text{ph}}/R_{\text{ph}} = 10^{-2}$. At lower temperature, the density dependence remains modest, $-1 \leq \alpha \leq 1$, but $\beta \simeq 12 - 16$. This steepness results from electron recombination with hydrogen, which exponentially limits all important opacity sources in this regime: the electron scattering opacity, the H^- photoionization opacity (electrons are required to form the anions), and the metal bremsstrahlung opacity. This leads to the flat segments in Figure 5. At even lower temperature, $T_{\text{eff}} < 3000 \text{ K}$, the completion of electron recombination ends the steep dependence of opacity on

temperature, and thus the $T_{\text{eff}} - \rho_{\text{ref}}$ curves again have a larger negative gradient at low T_{eff} (high ρ_{ref}).

The $T_{\text{eff}} - \rho_{\text{ref}}$ relation also depends on $H_{\text{ph}}/R_{\text{ph}}$. For a given effective temperature, if the photosphere scale height is small, a higher density will be needed to provide the same optical depth, and thus the curves with lower $H_{\text{ph}}/R_{\text{ph}}$ are located higher in the figure. We will return to this point when we discuss the simulation results in Section 5.2.

5.2. Numerical temperature profile

We conduct a grid of simulations with $L = 1.47 \times (10^{43}, 10^{44}, 10^{45}) \text{ erg s}^{-1}$ and a range of ρ_{ref} to cover the luminosities and colors of LRDs. The chosen values of luminosity correspond to the Eddington luminosity of a black hole mass of 10^5 – $10^7 M_{\odot}$, though we reiterate that our model does not stipulate or require $L = L_{\text{Edd}}$.

For each parameter set, we calculate the initial temperature using the radiative diffusion equation dominated by the electron scattering opacity and the power-law density profile in Equation (9). We obtain

$$T^4(r) \simeq \frac{3\kappa_{\text{es}}L}{10\pi ac} \rho_{\text{ref}} R_{\text{ref}}^{3/2} r^{-5/2}. \quad (12)$$

This is accurate when $r \ll R_{\text{ph}}$ and $T \gg T_{\text{eff}}$. We choose the inner boundary, R_{inner} , to be sufficiently optically thick (Rosseland mean optical depth greater than 100), and use Equation (12) to set the inner boundary condition of the radiation that has an energy density equal to $aT^4(R_{\text{inner}})$ and flux equal to $L/(4\pi R_{\text{inner}}^2)$.

In the remainder of this subsection, we describe the results from the gray simulations. The left panel of Figure 6 shows the temperature profiles for $L = L_{\text{Edd}}(10^6 M_{\odot})$. We also show the effective opacity κ_{eff} at 5000 Å calculated from the temperature profiles and the corresponding optical depth $\tau_{\text{eff}}(5000 \text{ Å})$ in the middle and right panels for diagnostic purposes, although wavelength-dependent opacities are not used in the gray simulations. The temperature decreases with radius, converging at large radii where the gas becomes optically thin and $E_{\text{rad}} = aT^4 \simeq L/4\pi cr^2$. These curves show a steep drop at $T \sim 8000 \text{ K}$. This occurs where the effective opacity reaches a maximum, as expected from radiative transport. Simulations with higher ρ_{ref} have higher temperature in the optically thick region at a given radius due to the higher optical depth.

Now, we focus on the photosphere properties indicated by the gray simulations and compare them with analytical estimates. On each curve, we find the locations where $\tau_{\text{eff}}(5000 \text{ Å}) = 1/4, 1/2$, and 1 and mark them with crosses in Figure 6. The radial distance between the first and last markers roughly indicates

the photosphere scale height H_{ph} (most clearly seen in the right panel). We use the gas temperature at $\tau_{\text{eff}}(5000 \text{ Å}) = 1/2$ to represent the photosphere temperature.⁴ We observe two trends. First, the photosphere temperature decreases with the reference density, as expected, and as in Figure 5. Second, while the photosphere scale height is comparable to the photosphere radius for $\rho_{\text{ref}} \geq 10^{-11.5} \text{ g cm}^{-3}$, H_{ph} becomes significantly smaller for lower ρ_{ref} . This shows that $H_{\text{ph}}/R_{\text{ph}}$ changes with ρ_{ref} , a complication not considered in our analytical estimates in Section 5.1.

We show the temperature at $\tau_{\text{eff}}(5000 \text{ Å}) = 1/2$ in Figure 5 to compare with our analytic estimates. The measured temperature decreases faster with ρ_{ref} than suggested by individual analytical curves. This is due to the change in $H_{\text{ph}}/R_{\text{ph}}$ in the simulations. The location of the measured points relative to the solid curves indicates that $H_{\text{ph}}/R_{\text{ph}} \sim 10^0$ for $\rho_{\text{ref}} \geq 10^{-11.5} \text{ g cm}^{-3}$ and $H_{\text{ph}}/R_{\text{ph}} < 10^{-1}$ otherwise, in agreement with Figure 6.

Although the photosphere temperature is empirically more sensitive to the accretion rate than analytical expectations, the simulations assume that the sphere is laminar with purely radiative energy transport. In reality, turbulent mixing can significantly boost $H_{\text{ph}}/R_{\text{ph}}$ to order unity for the cases with small photosphere scale heights. Turbulent energy dissipation in the optically thin region could do the same as well, by smoothing out the temperature profile. Simulations considering these additional effects are likely to achieve better agreement with the analytical curve of $H_{\text{ph}}/R_{\text{ph}} \sim 1$.

5.3. Numerical continuum spectra and comparison to observation

As we described in Section 5.1, the free parameters in our sphere scenario are the total luminosity L , defined in Equation (6), and a reference density ρ_{ref} , whose physical meaning is defined in Equation (9) and discussed in the text above and below the equation. Figures 7 and 8 show numerical continuum spectra from the multigroup simulations for a range of L and ρ_{ref} . In the background, we plot the same collection of LRD spectra as in Figure 4. The optical continuum luminosity of these LRDs ranges from 10^{43} to $10^{45} \text{ erg s}^{-1}$ (no dust attenuation is included here), approximately corresponding to the Eddington luminosity of black holes of mass from 10^5 to $10^7 M_{\odot}$.

⁴ Empirically, we find that the optical continuum is better approximated by a blackbody of the temperature at $\tau_{\text{eff}}(5000 \text{ Å}) = 1/2$ instead of $2/3$.

Figure 6. Temperature (left) from gray simulations of the sphere model with $L = L_{\text{Edd}}(10^6 M_{\odot})$. The effective opacity and optical depth at 5000 Å (mid, right) are calculated using the temperature profiles. Dark colors indicate high ρ_{ref} and hence high accretion rate. The three crosses on each curve mark the locations where $\tau_{\text{eff}}(5000 \text{ Å}) = 1/4, 1/2,$ and 1 to indicate the photosphere location and its scale height.

Figure 7. Continuum spectra from sphere models at a total luminosity $L = L_{\text{Edd}}(10^6 M_{\odot}) = 1.47 \times 10^{44} \text{ erg s}^{-1}$. Model spectra are color-coded by the reference density, ρ_{ref} , a proxy for the Eddington ratio (Equation (10)) and the photosphere density ($\rho_{\text{ref}} \sim \rho_{\text{ph}}$ if $T_{\text{eff}} \sim 5000 \text{ K}$). A collection of observed LRD spectra are shown in the background for comparison.

Our model curves in each figure exhibit the same bolometric luminosity by construction. The optical color reddens as ρ_{ref} increases, in agreement with the decreasing photosphere temperature measured in Section 5.2. At 3645 Å, almost all model spectra show a strong Balmer break with flux contrast on the order of a few. This is expected from the photosphere density of the spherical models (see the horizontal axis range of Figure 5, where $\rho_{\text{ref}} \sim \rho_{\text{ph}}$ if $T_{\text{eff}} \sim 5000 \text{ K}$). Some other discontinuities are present at shorter wavelengths as a result of metal photoionization. The jump in some spec-

Figure 8. Same as Figure 7, but for the models with $L = L_{\text{Edd}}(10^7 M_{\odot})$.

tra at 8200 Å corresponds to the Paschen limit and is physical; this is possible in the presence of scattering opacity (A. Schuster 1905; A. B. Underhill 1949). The model spectra of $L = L_{\text{Edd}}(10^5 M_{\odot})$ appear similar to those of higher masses except for their lower bolometric luminosities, and we do not plot them for brevity.

To compare with observation in more detail, in Figure 9, we select four sources with strong Balmer breaks, UNCOVER-45924, RUBIES-UDS-154183, RUBIES-UDS-40579, and RUBIES-UDS-31747. The first source is discovered in the UNCOVER survey (R. Bezanson et al. 2024), photometrically selected (I. Labbe et al. 2025), and studied in detail with high-SNR NIRSPEC/PRISM spectroscopy (I. Labbe et al. 2024), known as one of the most optically luminous LRDs observed so far. The latter three sources are ob-

Figure 9. Continuum spectra from spherical models compared to four LRD spectra showing strong Balmer breaks. The names of the observed objects are annotated. The model and observed spectra of UNCOVER-45924 and RUBIES-UDS-154183 are shifted up by 10 for visual clarity. The parameters for the four model curves are $(L, \rho_{\text{ref}}) = (7.4 \times 10^{44}, 2.0 \times 10^{-12})$, $(1.8 \times 10^{44}, 2.3 \times 10^{-12})$, $(4.4 \times 10^{44}, 5.5 \times 10^{-12})$, and $(7.4 \times 10^{43}, 1.6 \times 10^{-12})$ (in CGS units) respectively, from top to bottom.

served as part of the RUBIES program (A. de Graaff et al. 2024). RUBIES-UDS-154183 shows an outstanding Balmer break strength exceeding the limit expected from any stellar population (A. de Graaff et al. 2025). RUBIES-UDS-40579 is known for its extreme red color and has been studied individually in B. Wang et al. (2025). RUBIES-UDS-31747 is the same object that we highlighted in Figure 4. These sources represent LRDs with strong Balmer breaks at different luminosities and colors. On top of them are the spectra interpolated from our parameter grid: we choose L to match the peak luminosities of each objects and then choose ρ_{ref} to match the optical color. These are not intended as rigorous fits of the observations, but the visual agreement demonstrates that the spherical model can reproduce a strong break and a red optical color simultaneously without invoking stellar populations or external gas or dust absorption. The model spectra have a discontinuity at the Balmer break instead of a smooth rollover as in the observed spectra because we do not consider the Balmer series near the break, which will blend and form quasi-continuum absorption in the presence of turbulent gas motion. At longer wavelengths, the model curves become somewhat bluer than the observed spectra⁵, and

⁵ Our model spectra, especially the reddest ones, have larger curvature than a blackbody in the optical (see also X. Lin

the small inverse Paschen break is not clear in the data. These discrepancies can be alleviated by extensions of our simplistic model, e.g., by allowing for a distribution of ρ_{ref} . This will produce a range of effective temperatures at the photosphere, which tends to boost the infrared flux and smooth out the inverse Paschen break (which disappears at high ρ_{ref} in our models) while maintaining the Balmer break. This will arise naturally if rotation breaks spherical symmetry and the infalling gas has a more oval shape.

Assuming $L = L_{\text{Edd}}$, the models in Figure 9 correspond to black hole masses on the order of 10^5 – $10^7 M_{\odot}$. However, we reiterate that models of super-Eddington accretion can have $L > L_{\text{Edd}}$, in which case the BH masses inferred for the LRDs would be yet smaller. These black hole masses are significantly lower than previous estimates of the population based on the broad H α line (e.g., R. Maiolino et al. 2024a; J. E. Greene et al. 2024). However, these works usually included substantial dust correction to the broad-line luminosity, which likely overestimated the black hole mass in light of the absence of dust re-emission. These measurements also assumed that the line was Doppler-broadened by virial motion of gas in the broad line region, whose size was calibrated with local Type-I AGNs, but it remains unclear whether the gas in the broad line region is virialized (A. King 2024) and whether the broad line region of LRDs follows the same radius–luminosity relation as that of Type-I AGNs (A. Lupi et al. 2024). In addition, the modest black hole masses suggested here may align better with the clustering measurements of LRDs (J. Matthee et al. 2024b; X. Lin et al. 2025; M. Carranza-Escudero et al. 2025) and with the host galaxy masses constrained from extended emission (C.-H. Chen et al. 2025b,a; R. Li et al. 2025) and narrow line dispersion (H. Übler et al. 2023; R. Maiolino et al. 2024b; B. Wang et al. 2025; X. Ji et al. 2025).

The reference densities are of the order 10^{-12} – $10^{-11} \text{ g cm}^{-3}$, with the photosphere densities spanning 10^{-13} – $10^{-11} \text{ g cm}^{-3}$. The range would likely widen in more realistic models that consider turbulence (see Section 5.2). These values are chosen to match the optical color of LRDs regardless of their Balmer break strength, but the strong Balmer break is ubiquitous in our models, as expected from Section 2. The model spectra

et al. 2025, in prep). When the gas is mostly neutral (e.g., $T \lesssim 5000 \text{ K}$ at $\rho = 10^{-12} \text{ g cm}^{-3}$), Rayleigh scattering will become the dominant opacity source at optical wavelengths (see P. Lenzuni et al. 1991, although they studied zero-metallicity gas). It preferentially suppresses short-wavelength spectral flux, similar to but more manifest than its role in metal-poor giant stars (R. Cayrel et al. 2004).

Figure 10. Balmer break strength and optical color of the sphere models (color-coded proportional to $\rho_{\text{ref}} L^{-1/2}$) compared to observation (blue points with error bars). The spherical model can explain the region below the measured points (due to filling by the UV component), consistent with the distribution of known LRDs.

for RUBIES-UDS-40579 and RUBIES-UDS-31747 have even more pronounced breaks than the data. However, our spherical model does not account for the UV continuum flux of LRDs, whose origin is still debated (e.g., J. E. Greene et al. 2024; G. Barro et al. 2024; R. P. Naidu et al. 2025; C.-H. Chen et al. 2025b; P. Rinaldi et al. 2024; C.-H. Chen et al. 2025a). Assuming that this component does not produce a stronger Balmer break than the model spectra here, the total flux will show a partially or completely filled Balmer break. In this case, the optical spectrum shown here represents the upper limit of the break strength generated by the spherical model. This also naturally places the inflection point of the V-shaped spectrum near the Balmer limit over a wide range of UV-to-optical luminosity ratios, suggesting a robust explanation for its observed location (D. J. Setton et al. 2024).

In Figure 10, we further quantify the model Balmer break strength and compare it to observation, including the same collection of observed LRDs that we showed in Figure 4 and RUBIES-UDS-154183. We follow A. de Graaff et al. (2025) to evaluate the observed Balmer break strengths and uncertainties with the flux density (f_ν) ratio at two bands, [4000, 4100] Å

and [3620, 3670] Å. To characterize the Balmer break from the models, we use the luminosity (L_ν) ratio in two wavelength bins, [4000, 4100] Å and [3640, 3645] Å. The blue band is narrower than the one used for the observed LRDs in order not to traverse the theoretical Balmer limit. We also quantify the optical color of the model and observed spectra. We follow D. J. Setton et al. (2024) and evaluate the model and observed flux densities within two top-hat filters, “B” in [4000, 4700] Å and “R” in [6700, 7400] Å. We exclude sources at $z > 6$ as their “R” band is not fully covered by JWST/NIRSpec. Our break strength and color measurements are broadly consistent with those reported in A. de Graaff et al. (2025) and D. J. Setton et al. (2024).

The model points are spread roughly along the diagonal of Figure 10, with redder optical colors correlating with stronger breaks. This trend persists even when $B - R > 2$, where the effective temperature falls below the optimal temperature in Figure 2. This is presumably because the atmosphere layer where $T \sim 5000$ K is not very optically thick even for the coolest models (see the right panel in Figure 6), so a Balmer break formed there can still manifest itself. At a given optical color, models with lower luminosities show slightly stronger breaks over most of the presented color range. Since this luminosity dependence is modest, we broadly term the area at or below the diagonal stripe of the model points as consistent with the models (when complemented with a UV component). The points denoting observed objects generally fall into this area, although RUBIES-UDS-154183 (A. de Graaff et al. 2025) lies at the boundary (see also Figure 9). In the current literature, this source is unmatched in the break strength except for “MoM-BH*-1” (R. P. Naidu et al. 2025), an LRD at $z = 7.76$ with a very similar Balmer break and continuum up to $\lambda_{\text{rest}} = 6000$ Å, the red edge of the available spectrum. Therefore, we find no significant inconsistency between the model and most, if not all, known LRDs in terms of the Balmer break strength.

6. DISCUSSION AND SUMMARY

This work aims to connect the observed Balmer break and optical redness of LRDs with the theoretical picture of super-Eddington accretion onto black holes. To this end, we have constructed idealized atmosphere models of super-Eddington accretion systems in a disk or spherical geometry (Figure 1) and conducted radiation transport calculations to study their continuum spectral properties. Our study contributes to a physically motivated interpretation of LRDs.

Our first conclusion is that a photosphere at $T \sim 5000$ K and $\rho < 10^{-9}$ g cm $^{-3}$ produces a Balmer break.

The underlying physics is the same as the well-known break feature in early-type stars, namely a discontinuity in opacity at the Balmer limit. The optimal photosphere temperature to produce the Balmer break increases with density as indicated by the opacity law (Figure 2). This is why our models produce strong Balmer breaks at lower effective temperatures than stellar atmospheres.

We further find that super-Eddington accretion systems naturally have $\rho < 10^{-9} \text{ g cm}^{-3}$ at the photosphere. This is true for both the disk (Equation (5)) and the sphere (Figure 5) scenarios. We conclude that a super-Eddington system will robustly produce a Balmer break if the photosphere is cool (Figures 4, 7–10).

The remaining question is the ubiquity of the cool photosphere, i.e. the optical redness of LRDs. We find that the sphere scenario gives an effective temperature of $4000 \text{ K} \lesssim T_{\text{eff}} \lesssim 6000 \text{ K}$ over a wide range of the reference densities, i.e., accretion rates (Figure 5). This is due to electron recombination producing a strong temperature dependence of the opacity, and is analogous to the origin of the Hayashi line in stellar models. Together, the sphere scenario naturally reproduces the optical color and the Balmer break of LRDs (Figure 9). By contrast, a standard thin disk model (which can be present in the outer parts of super-Eddington accretion flows) would explain the optical redness of LRDs only if the disk is truncated at the radius where the effective temperature is $\sim 5000 \text{ K}$. We are unsure why this should generically be the case.

6.1. Comparison to prior work

Our explanation of the Balmer break is related to the work of K. Inayoshi & R. Maiolino (2025), who proposed that a dense gas shell, where neutral hydrogen is collisionally excited to the $n = 2$ state, absorbs photons bluer than the Balmer limit and thus imprints a Balmer break on an otherwise featureless continuum spectrum. They inferred the properties of the proposed gas shell using CLOUDY models, a method subsequently adopted in various case studies (X. Ji et al. 2025; R. P. Naidu et al. 2025; A. de Graaff et al. 2025; A. J. Taylor et al. 2025). The photospheric Balmer break in our models has a similar microphysical origin and does not contradict the absorbing gas shell picture. However, in the language of CLOUDY, our work does not need to assume an “incident” radiation spectrum: the continuum flux and the Balmer break arise self-consistently from radiation transport calculations given a physically motivated model of the gas distribution. This allows us to predict the continuum color from atmosphere models. We also note that our method can handle large

scattering optical depths expected in super-Eddington accretion flows, which CLOUDY presently cannot model (see Section 10.8 in the documentation “Hazy1”, G. J. Ferland et al. 2023).

When this work was close to completion, D. Kido et al. (2025) proposed that an optically thick envelope around the black hole produces an effective temperature of $T_{\text{eff}} \sim 5000\text{--}7000 \text{ K}$, close to the Hayashi limit (C. Hayashi 1961). Both D. Kido et al. (2025) and we argue that for an optically thick spherical system, hydrogen recombination produces a large change in opacity with temperature and thus sets the effective temperature observed. However, our work differs from D. Kido et al. (2025) in that we carry out detailed radiation transport calculations to predict spectra that are similar to those observed. In addition, we argue that the Balmer break and the continuum emission can be produced roughly at the same location in the accretion flow photosphere, rather than requiring a separate dynamical component at larger radii to produce the Balmer break. The importance of the change in opacity at hydrogen recombination emphasized here and in D. Kido et al. (2025) in the context of LRDs was in fact predicted in the “quasi-star” model (M. C. Begelman et al. 2008) for the early growth of supermassive black hole seeds. M. C. Begelman et al. (2008) also highlighted the analogy to the Hayashi line in stellar models that we have emphasized.

6.2. Caveats and future directions

All models in this work have assumed LTE, and our spectral calculations do not account for lines or gas motion. Detailed spectral predictions, including the emission and absorption lines observed from LRDs, require non-LTE radiation transport and likely depend on the atmosphere structure. However, the physical analogy between the photosphere of spherical super-Eddington accretion flows and that of stars suggests possible observational similarity in their spectral features, of which the Balmer break is just one example. We anticipate that future high-resolution spectroscopy can probe the density, temperature, metallicity, and kinematics of the LRD photosphere, which will test our scenarios directly (see an interesting observational case in X. Lin et al. 2025, in prep).

Despite the success of our model in reproducing aspects of the observed spectra of LRDs, many open questions remain. Returning to the cartoon in Figure 1, while we can reproduce a Balmer break from a disk geometry, it is unclear how to truncate the disk at $T_{\text{eff}} \sim 5000 \text{ K}$, which is required to reproduce the optical redness of the LRDs (Figure 4). A structural change of the disk, due to the opacity or other properties of

the gas at this particular effective temperature, might generate such a truncation. Specifically, the disk could potentially become quasi-spherical at small radii, leading to a composite disk-sphere scenario. However, we have not explored at what radius this transition should occur and whether it is connected to an effective temperature of ~ 5000 K. In the sphere scenario, we have remained agnostic about the exact cause of the geometric thickness. Radiation pressure alone can only support a geometrically thick disk within a radius $\sim 10\lambda_{\text{Edd}}R_g$, which is generally smaller than the photospheric radius in our spherical models. If, however, dense gas is fueled from larger scales with a wide range of angular momenta, or if optically thick winds from small radii modify the dynamical and emission properties of the gas at large radii, the spherical structure may be maintained at the scale of the ~ 5000 K photosphere.

We have yet to account for the origin of the broad emission lines of LRDs. Super-Eddington accretion theory and simulations generically predict rapid outflows with a much lower density than other regions of the flow (e.g., N. I. Shakura & R. A. Sunyaev 1973; Y.-F. Jiang et al. 2019); these may also be quite clumpy (H. Kobayashi et al. 2018), as is the case for radiation-driven stellar winds (e.g., S. P. Owocki et al. 2004). Such lower-density regions may expose hot gas at smaller radii, enabling ionizing photons to escape and power the broad lines. Indeed, our spherical models with lower reference density (which could correspond to a higher-speed component at a given mass flow rate) have significantly higher effective temperatures (Figures 5 and 7). An appropriate superposition of a range of flow velocities and densities could plausibly explain the full spectra of LRDs from the UV to the near-infrared, including the broad emission lines.

The gas density and velocity distributions are undoubtedly much more complex than our simple models, which may be responsible for the complex broad line profiles, including Balmer absorption, of many LRDs (e.g., R. Maiolino et al. 2025; D. D. Kocevski et al. 2024; I. Juodžbalis et al. 2024). In addition, super-Eddington accretion flows may explain the X-ray weakness of LRDs (F. Pacucci & R. Narayan 2024; E. Lambrides et al. 2024; K. Inayoshi et al. 2024; P. Madau & F. Haardt 2024; A. Trinca et al. 2024); while this was recently questioned in A. Sacchi & A. Bogdan (2025), we note that quantitative X-ray predictions depend on computational methods, the assumed gas geometry, the bolometric correction, and physical parameters such as the Eddington ratio. Ultimately, the simple super-Eddington models presented here will need to be supplemented by real-

istic three-dimensional simulations tailored for LRDs—those with physical parameters relevant to supermassive black holes and enough spatial dynamic range to include the regions responsible for emission from the X-ray (if present) to the optical-infrared (we expect that the optical-infrared emission arises at large radii where current simulations are not in statistically steady state). The results of super-Eddington simulations may be particularly sensitive to the geometry of the accreting gas. The gas is possibly much less ordered than standard rotating initial conditions used in most simulations, which could suppress the X-ray emission and the viewing angle dependence of the spectra. Drawing initial conditions from simulations of high-redshift galaxies could inform more physical models of super-Eddington accretion in LRDs.

The interpretation favored in this paper is one in which LRDs are powered by relatively low-mass black holes that are highly super-Eddington. This suggests an important phase of black hole growth, with potential evolutionary links to the initial seeding stage (K. Inayoshi 2025; K. Inayoshi et al. 2020; M. Volonteri et al. 2021; see also the quasi-star scenario in M. C. Begelman et al. 2008; E. R. Coughlin & M. C. Begelman 2024). Although significant work remains, our work points to LRDs as an exciting and unique new probe of black hole evolution and demographics.

APPENDIX

A. VERTICAL STRUCTURE OF THE DISK MODEL

We consider a radiation-dominated thin disk. At each annulus at radius r , the equations include hydrostatic equilibrium,

$$\frac{1}{3} \frac{dE_{\text{rad}}}{dz} = -\Omega^2 \rho z, \quad (\text{A1})$$

definition of the optical depth,

$$\frac{d\tau}{dz} = -\kappa_R \rho, \quad (\text{A2})$$

radiative energy transport,

$$\frac{1}{3} \frac{dE_{\text{rad}}}{d\tau} = \frac{F}{c}, \quad (\text{A3})$$

and thermal equilibrium,

$$\frac{dF}{d\tau} = -\frac{Q}{\kappa_R \rho}. \quad (\text{A4})$$

Here, z is the vertical coordinate, with $z = 0$ being the midplane location, $E_{\text{rad}} \equiv aT^4$ is the radiation energy density, $\Omega \equiv \sqrt{GM_{\text{BH}}/r^3}$ is the Keplerian angular velocity, F is the vertical radiation flux, κ_R is the Rosseland-mean opacity, and Q is the heating rate per unit volume due to accretion. Consistent with previous radiation hydrodynamic simulations of radiation-dominated accretion disks (S. Hirose et al. 2009), we assume $Q \propto \rho\tau^{-1/2}$. The boundary conditions are $\{\rho = 0, F = \sigma T_{\text{eff}}^4, E = aT_{\text{eff}}^4/2\}$ at $\tau = 0$, where T_{eff} is given by Equation (3), and $\{z = 0, F = 0\}$ at $\tau = \tau_m$, where $\tau_m \gg 1$ is the midplane optical depth to be determined later. We have five boundary conditions for the four equations; the one extra condition serves to fix the normalization factor of Q .

The above system of equations is challenging to solve even numerically due to the complex temperature and density dependence of the opacity. Moreover, we expect the solution to involve dynamically unstable density inversion (Appendix A.1). Therefore, we adopt an approximate solution as follows. We first assume that $\kappa_R = \kappa_{\text{es}}$, which is accurate in the ionized disk interior. This allows us to solve Equation (A4) and then Equation (A3) analytically:

$$F(\tau) = \sigma T_{\text{eff}}^4 \left(1 - \sqrt{\frac{\tau}{\tau_m}} \right), \quad (\text{A5})$$

$$E_{\text{rad}}(\tau) = \frac{1}{2} a T_{\text{eff}}^4 \left(1 + \frac{3}{2} \tau - \sqrt{\frac{\tau}{\tau_m}} \tau \right), \quad (\text{A6})$$

and then Equations (A1)(A2) imply

$$\rho(z) = \frac{2\tau_m}{\kappa_{\text{es}} H} \left(1 - \frac{z}{H} \right), \quad (\text{A7})$$

where $0 \leq z \leq H$, and

$$H = \frac{\kappa_{\text{es}} \sigma T_{\text{eff}}^4}{\Omega^2 c} \quad (\text{A8})$$

is the height at which the density drops to zero. Note that ρ monotonically decreases with z , so this solution excludes any density inversion. The temperature profile follows from $E_{\text{rad}} = aT^4$. Next, we partially relax the assumption of $\kappa_R = \kappa_{\text{es}}$. Using the density profile, Equation (A7), we calculate $\tau(z)$ from Equation (A2) using a realistic table of the Rosseland-mean opacity $\kappa_R(\rho, T)$. The optical depth profile then gives $F(z)$ and $E_{\text{rad}}(z)$ from Equation (A5)(A6). In effect, if we assume $Q \propto \kappa_R \rho \tau^{-1/2}$ instead of $Q \propto \rho \tau^{-1/2}$ (being still consistent with S. Hirose et al. 2009, where κ_R is dominated by κ_{es}), then our approximate solution will strictly satisfy Equations (A2)(A3)(A4) with realistic opacities, agree with Equation (A1) in the disk interior, and avoid density inversion near the disk surface when $T < 10^4$ K.

The remaining undetermined quantity is τ_m . We use the α -disk prescription, requiring

$$\frac{\alpha}{\Omega} \int_0^H \frac{1}{3} E_{\text{rad}} dz = \frac{\dot{M}}{6\pi}, \quad (\text{A9})$$

which is generalized from the standard, vertically integrated α -disk model. We fix $\alpha = 0.1$ in this work. This additional equation determines τ_m and completes our analytical model. In practice, τ_m is determined iteratively. For each set of independent parameters (M, λ_{Edd}), we explore a range of radii that give effective temperatures around 5000 K. For each r , we make an initial guess for τ_m , obtain $F(\tau), E_{\text{rad}}(\tau), \rho(z)$, and $\tau(z)$, then compare the two sides of Equation (A9) and update τ_m until this equation is satisfied. Finally, we collect $\rho(z), Q(z), T(z)$, and $F(z)$ and apply them to the simulations. The density profile is fixed. The heating rate is implemented as a fixed explicit energy source term in ATHENA++. The last two terms serve as initial conditions, as described in Section 3.1.

A.1. A note on density inversion

We have described the equations satisfied by a thin disk annulus under hydrostatic equilibrium and radiative energy transport but did not solve them exactly. The choice is technical and physical.

Figure 11. Comparison of model disk vertical profiles for the case $M_{\text{BH}} = 10^7 M_{\odot}$, $\lambda_{\text{Edd}} = 1$. The vertical axis is scaled linearly below $10^{-12} \text{ g cm}^{-3}$ and logarithmically above. Solid curves denote the full solution described in Appendix A.1. Dashed curves denote the approximation described in Appendix A and applied in the main text. The full model shows density inversion at radii $r \geq 10^{3.2} R_g$, which is avoided in the approximate model.

The main challenge in solving the equations is the need to obtain ρ implicitly from κ_R : we cannot directly update ρ because it does not appear on the left-hand side of Equations (A1)–(A4). This requires mapping κ_R to ρ at a given temperature. But this is not always possible: sometimes, no value of ρ in the entire opacity table will give the desired κ_R .

This issue will be partially circumvented if we include the gas pressure in the hydrostatic equilibrium equation, i.e., if we replace Equation (A1) with

$$\frac{d}{dz} \left(\frac{E_{\text{rad}}}{3} + \frac{\rho k_B T}{\mu m_p} \right) = -\Omega^2 \rho z. \quad (\text{A10})$$

This introduces ρ to the derivative term, which allows us to find ρ using standard techniques of initial value problems and eliminates the need to infer ρ from κ_R . However, Equation (A10) will become stiff in the super-Eddington regime, where $E_{\text{rad}} \gg \rho k_B T / \mu m_p$, and evaluating the derivative of ρ will result in catastrophic cancellation. In practice, we have successfully solved the system of Equations (A10)(A2)(A3)(A4) when $M_{\text{BH}} = 10^7 M_{\odot}$, $\lambda_{\text{Edd}} = 1$ but not when $M_{\text{BH}} = 10^7 M_{\odot}$, $\lambda_{\text{Edd}} = 10^2$.

Even without these technical difficulties, the solution may show an unstable density inversion. We show this by solving Equations (A10)(A2)(A3)(A4) numerically in the case $M_{\text{BH}} = 10^7 M_{\odot}$, $\lambda_{\text{Edd}} = 1$. Figure 11 presents the solution for a range of radii in solid curves. For comparison, the dashed curves show the approxi-

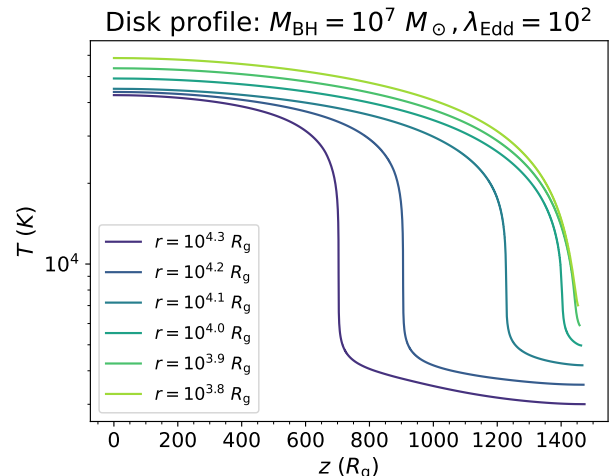

Figure 12. Disk vertical temperature profile from the gray simulations. The disk has $M_{\text{BH}} = 10^7 M_{\odot}$ and $\lambda_{\text{Edd}} = 10^2$. Each curve represents an individual simulation of an annulus.

mate solutions that we developed above in Appendix A and applied to calculate the spectra in Figure 4. At $r \geq 10^{3.2} R_g$, or $T_{\text{eff}} \leq 7606 \text{ K}$, a local maximum in density at $T < 10^4 \text{ K}$ appears in the full solution, implying a disk surface layer that is denser than the interior. Previous work on sub-Eddington disks has noted similar behavior (I. Hubeny et al. 2000). This configuration will unlikely be sustained in a realistic disk due to the Rayleigh-Taylor instability. On the other hand, in the approximate solutions, the density monotonically increases with temperature and hence decreases with height throughout each annulus; see Equation (A7).

In summary, we adopt the approximate model because it is computationally tractable in the super-Eddington regime and because it does not show any physically unstable density inversion. As a caveat, we do not expect the model to represent a realistic annulus structure, which requires dedicated simulations especially in the presence of turbulence.

A.2. Temperature structure from gray simulations

For completeness, this subsection reports the temperature profiles from gray simulations in the disk models. Figure 12 shows the temperature of a range of annulus radii in the case with $M_{\text{BH}} = 10^7 M_{\odot}$, $\lambda_{\text{Edd}} = 10^2$. For each annulus, the temperature decreases with height, which is required for radiative energy transport. The right end of each curve reaches $T(\tau = 0) = 2^{-1/4} T_{\text{eff}}$ (relative error $< 4\%$), as expected from Equation (A6). For those annuli with low T_{eff} , the temperature decreases dramatically with z at $T \sim 8000 \text{ K}$ and then flattens due

to variations in the Rosseland- and Planck-mean opacities with temperature.
