ABSTRACT

Using cosmological radiation-hydrodynamical simulations, we study the effect of accreting supermassive black holes (SMBHs) on nearby dark-matter (DM) haloes in the very early universe. We find that an SMBH with a spectral energy distribution (SED) extending from the near-ultraviolet to hard X-rays, can produce a radiation background sufficient to delay gravitational collapse in surrounding DM haloes until up to $10^7 M_{\odot}$ of zero-metallicity gas is available for the formation of Population III (Pop III) stars or direct-collapse black holes (DCBHs). We model three scenarios, corresponding to an SMBH located at physical distances of 10, 100, and 1000 kpc from the Pop III host DM halo. Using these three scenarios, we use the SED to compute self-consistent photoionization, photoheating, and photodissociation rates. We include the effects of Compton scattering and gas self-shielding. The X-ray portion of the spectrum maintains an elevated free-electron fraction as the gas collapses to high density. This stimulates H_2 formation, allowing the gas to cool further while counteracting the dissociation of H_2 by Lyman-Werner radiation. As a result, a large cluster of Pop III stars is expected to form, except in the case with the most intense radiation in which a DCBH may instead form. Our simulated Pop III clusters have comparable $He\ II\ \lambda 1640$ luminosities to the recently discovered Pop III host candidate near GN-z11, observed by the *James Webb Space Telescope*. In two of the scenarios we consider, the resulting clusters could be detectable using the telescope’s NIRSPEC instrument out to $z \sim 15$.

Key words: stars: Population III – hydrodynamics – galaxies: high-redshift – quasars: supermassive black holes

1 INTRODUCTION

Population III (Pop III) stars are the as-of-yet unobserved first generation of stars in the universe that are expected to be formed from primordial gas. They are an exciting target for the *James Webb Space Telescope* (JWST) (Gardner et al. 2006, 2023; McElwain et al. 2023), which contains several infrared-detecting instruments that allow the telescope to observe high-redshift phenomena. Recently, a possible $He\ II\ \lambda 1640$ emission line, an expected spectral signature of Pop III stars, was observed in the vicinity of the galaxy GN-z11 at $z = 10.6$ (Maiolino et al. 2024b). Another galaxy, LAP1-B, observed at $z = 6.6$, has very low metallicity and a hard ionizing spectrum (Nakajima et al. 2025) that aligns with theoretical predictions for Pop III stars. Fujimoto et al. (2025) presented an upper limit on the luminosity function of Pop III galaxies at $z = 6-7$, and Hsiao et al. (2025) observed 12 very low-metallicity galaxy candidates at $z \sim 5-7$, two of which have metallicities $Z < 10^{-2} Z_{\odot}$. Low-metallicity galaxies have also been observed at lower redshifts. Mondal et al. (2025) observed $He\ II\ \lambda 1640$ emission at $z = 2.98$, possibly powered by small pockets of Pop III stars in a partially metal-enriched galaxy. Cai et al. (2025) also discovered the galaxy MPG-CR3 at $z = 3.19$, with a metallicity $Z < 8 \times 10^{-3} Z_{\odot}$ and an estimated stellar mass of $6.1 \times 10^5 M_{\odot}$.

Previous work shows that the characteristics of Pop III clusters would be strongly shaped by their radiative environment. An H_2 -

dissociating Lyman-Werner (LW) background can prevent the gas from cooling, increasing the initial mass function (IMF) of the stars formed, and with a high enough flux inducing the formation of a direct-collapse black hole (DCBH; Latif et al. 2014). Other work also showed that an ionizing ultraviolet (UV) background could delay Pop III formation until lower redshifts (Visbal et al. 2017; Kulkarni et al. 2019). Park et al. (2021) showed that a much weaker X-ray background could elevate the free-electron fraction in the collapsing gas, catalysing H_2 formation, which boosts Pop III star formation in low-mass dark matter (DM) haloes.

Past work has also studied Pop III formation in the most extreme radiative environments. Johnson & Aykotalp (2019) showed, using a simplified one-zone model, that a monochromatic 1000 eV flux from the quasar of a nearby supermassive black hole (SMBH) could also induce the formation of a DCBH within 100 kpc of the host DM halo. Prole et al. (2024) also showed that a DM halo merger can increase the gas temperature of the resultant halo through dynamical heating, increasing the initial mass function (IMF) of the objects that form without a radiation background. A related scenario, although not involving Pop III stars, was observed by Balashev et al. (2025), which presented observations of two merging galaxies (one of which contains a powerful quasar) at $z = 2.7$. In the quasar host’s companion, compact, high-density gas clouds were found, indicating that UV from the quasar dissociated most of the molecular gas, leaving only high-density regions that were shielded from the quasar. Similarly, Suzuki et al. (2025) showed that Lyman- α emitting and continuum-selected galaxies have lower densities when they are near quasars,

* E-mail: emf@lanl.gov

and [Đurovičková et al. \(2025\)](#) observed a Lyman- α emitter candidate at a projected distance of 29 kpc from the quasar PSO J158-14.

Here we extend previous work by running 3D radiation-hydrodynamical simulations to model the radiative feedback of an active galactic nucleus (AGN) on the formation of Pop III stars in neighbouring regions. We use a standard composite quasar SED ([Haardt & Madau 2012](#)) to model the entire spectrum, computing self-consistent photodissociation, photoionization, and photoheating rates. We also account for Compton scattering and inverse Compton scattering self-consistently with this spectrum. In Section 2 we discuss our simulations and in Section 3 we present the results. In Section 4 we determine the specific objects that would form after gravitational collapse in each scenario, and their detectability with *JWST*. Finally, in Section 5 we summarize our findings. We assume a Λ CDM cosmology with the following parameters from [Planck Collaboration et al. \(2016\)](#): $\Omega_M = 0.309$, $\Omega_\Lambda = 0.691$, $\Omega_b = 0.0486$, $h = 0.677$, $\sigma_8 = 0.816$, and $n_s = 0.968$.

2 SIMULATIONS AND METHODS

2.1 Simulation Setup

Using ENZO, ([Bryan et al. 2014](#)), a cosmological adaptive mesh refinement (AMR) radiation hydrodynamics code, we initialized a periodic box at $z = 200$ with a comoving size of $(10 \text{ Mpc}/h)^3$. Initial conditions were generated with MUSIC ([Hahn & Abel 2011](#)). First, we ran a simulation with resolution 128^3 (128 cells per side) and no AMR. We tracked the largest DM halo using the halo finder in yt ([Turk et al. 2011](#)), then restarted the simulation at $z = 200$ centred on this largest halo. By $z = 12$, this halo reached a mass of $\sim 2.5 \times 10^9 M_\odot$. During the second run, we tracked the evolution of 12 species (H, H^+ , He, He^+ , He^{++} , e^- , H_2 , H_2^+ , H^- , D, D^+ , and HD).

The impact of the AGN radiation on the primordial gas was modelled using three different scenarios (described in Section 2.2) as an isotropic radiation background. To avoid discontinuities in the simulation, we gradually ramped up the intensity of the background using a logistic function. The radiation backgrounds reached full intensity at $z = 37$, in order to ionize the entire box before gravitational collapse. [Visbal et al. \(2017\)](#) showed that the time at which the radiation background is turned on has no significant effect on the Pop III star clusters that form, as long as the background can completely ionize the intergalactic medium.

In our second set of runs with the radiation background turned on (with the same box size as the first run), the base resolution remained at 128^3 with the inner 20% of the box being set to an effective resolution of 512^3 . AMR was also turned on in the central region based on the local Jeans length (resolved by 16 cells across), and a 1.5 overdensity criterion for both baryons and dark matter. At the highest densities, the simulations had up to 18 levels of refinement from the base grid, allowing a maximum physical resolution of 0.11 comoving pc. The simulations were stopped upon reaching a threshold gas density of $10^{-18} \text{ g cm}^{-3}$, after which an unresolvable runaway collapse to stellar densities would occur.

2.2 Quasar Background

To compute our quasar background, we assume an SMBH with bolometric luminosity of $1.26 \times 10^{47} \text{ erg s}^{-1}$ (L_{bol}), corresponding to an SMBH of $10^9 M_\odot$ accreting at the Eddington limit. We simulate three different scenarios. In Scenario A, we adopt a uniform background radiation field with a flux corresponding to that which would

Figure 1. The virial mass of the growing DM halo (used in all three scenarios) is plotted against redshift and virial temperature. The redshifts at which runaway gravitational collapse happens ($z = 24.99$, 15.46 , 12.63) for scenarios A, B, and C, respectively, are labelled.

be produced by the AGN at a distance $r = 1000$ kpc away from our DM halo. In Scenario B, the radiative flux corresponds to that produced at a distance of $r = 100$ kpc away, and Scenario C corresponds to a distance of $r = 10$ kpc. We use the quasar spectrum at $z = 0$ from [Haardt & Madau \(2012\)](#), which extends from $3 - 10^6$ eV, to compute a piecewise power law fit, which is normalized to the black hole mass and distance.

We model the three backgrounds as a set of isotropic photoionization, photoheating, photodissociation, and Compton scattering rates calculated using our chosen spectrum. Isotropic photoionization rates are calculated (in units of s^{-1}) using the following,

$$\gamma = \frac{L_{\text{bol}}}{4\pi r^2} \int_{\nu_0}^{\infty} \frac{\sigma_\nu f_\nu d\nu}{h\nu}, \quad (1)$$

where h is Planck's constant, σ_ν is the photoionization cross section of each respective species as a function of frequency, f_ν is the fraction of photons at a given frequency (where the total is normalized to one), and ν_0 is the minimum ionization frequency of each respective species. The corresponding photoheating rates are calculated as

$$\Gamma = \frac{L_{\text{bol}}}{4\pi r^2} \int_{\nu_0}^{\infty} \frac{\sigma_\nu f_\nu (\nu - \nu_0) d\nu}{\nu}. \quad (2)$$

Photoionization cross sections for the two hydrogenic species (H and He II) were taken from [Osterbrock & Ferland \(2006\)](#), and cross sections for He I were taken from [Verner et al. \(1996\)](#). The photodissociating LW flux was calculated by normalizing the fraction of photons in the 11.2 – 13.6 eV range to the bolometric luminosity of the SMBH. Appendix A lists the specific rates used in the simulations, based on these calculations.

We also include Compton heating, based on [Rybicki & Lightman \(1986\)](#), where the energy deposited to an electron in one Compton scattering is

$$\Delta E = \frac{\langle h\nu \rangle}{m_e c^2} (\langle h\nu \rangle - 4kT), \quad (3)$$

where $\langle h\nu \rangle$ is the mean photon energy for our spectrum (26.95 eV), m_e is the mass of the electron, c is the vacuum light speed, k is the Boltzmann constant and T is temperature. The rate of energy

deposited per unit volume is then

$$\frac{dE}{dt} = \frac{\langle h\nu \rangle}{m_e c^2} (\langle h\nu \rangle - 4kT) \sigma_T n_e F_\gamma, \quad (4)$$

where $F_\gamma = L_{\text{bol}} / (4\pi r^2 \langle h\nu \rangle)$, σ_T is the Thomson cross section, and n_e is the number density of free electrons.

We include shielding for photoionizations and photoheating, using a default ENZO setting, although the average photoionization cross sections used for the shielding are recalculated based on the quasar spectrum (Haardt & Madau 2012). We also include shielding for H_2 dissociations, based on Wolcott-Green et al. (2011):

$$f_{\text{shield}}(N_{\text{H}_2}, T) = \frac{0.965}{\left(1 + \frac{x}{b_5}\right)^{\alpha(n,T)}} + \frac{0.035}{(1+x)^{0.5}} \times \exp\left[-8.5 \times 10^{-4} (1+x)^{0.5}\right], \quad (5)$$

where $x \equiv N_{\text{H}_2} / 5 \times 10^{14} \text{cm}^{-2}$, $b_5 \equiv b / 10^5 \text{cm s}^{-1}$, $\alpha = 1.1$, N_{H_2} is the H_2 number density, and b is the Doppler broadening parameter $\sqrt{\frac{2kT}{m}}$, where m is the mass of an H_2 molecule.

3 RESULTS

Here we present the results of the three simulations of the AGN at 1000, 100, and 10 kpc, which we refer to as Scenarios A, B, and C, respectively. Figure 1 shows the build-up of dark matter mass in the simulated halo as a function of redshift. Runaway gravitational collapse of the primordial gas occurred at $z = 24.99, 15.46,$ and 12.63 , for Scenarios A, B, and C, respectively. Our DM halo grew to a mass of $2.23 \times 10^9 M_\odot$ at the time of runaway gravitational collapse in Scenario C. In Scenarios B and C, Compton scattering from the quasar background was powerful enough to keep the free electrons and photons in thermal equilibrium, meaning that the gas stayed ionized, preventing it from cooling via atomic electron transitions, and keeping it at a temperature of 78,000 K, corresponding to the median photon energy of 26.95 eV of our adopted spectrum. The virial temperature (Barkana & Loeb 2001), also plotted in Figure 1, grew with the DM halo mass roughly until it reached the temperature of the gas for each respective scenario, at which point a runaway gravitational collapse occurred.

Figure 2 shows density, temperature, free-electron fraction, and H_2 fraction as a function of radial distance from the DM halo centre at the redshift of collapse. Once temperatures dropped to $\sim 10^4$ K, recombination occurred, allowing the gas to cool further through electronic transitions and for shielding of the ionizing portion of the spectrum. However, even as the gas collapsed, the free-electron fraction remained high in the scenarios with the highest-intensity radiation fields (B and C), as shown in the bottom left panel of Figure 2. The free electrons, in turn, catalysed the formation of H_2 through the reactions (Galli & Palla 1998; Glover 2005):

Figure 3 shows density and temperature slices of each scenario at the moment the simulations were stopped. The plot shows that hydrogen deuteride (HD) cooling allowed the gas to reach the temperature floor set by the cosmic microwave background ($T_{\text{CMB}} \sim 70$ K) in Scenario A, although in Scenarios B and C the LW flux was

sufficient to noticeably reduce the H_2 (and HD) fraction, precluding this efficient cooling process.

In Figure 4, we estimate the mass enclosed in each of the three scenarios. This mass is determined by computing the infall time for each cell based on its radial velocity relative to the location of the cell with the highest gas density. We assume that gas from outflowing cells is not accreted, and therefore it is not included in the infall time calculation. We find that the mass enclosed increases along with the radiation background. This is consistent with the fact that in each respective scenario, more gas is available because the DM halo has grown larger.

The mass available to form Pop III stars or DCBHs in each scenario can be computed based on the mass that collapses within the time limit for Pop III formation. The largest stars formed would have a lifetime of around 3 Myr, after which Pop III star formation depends on the metal mixing time-scale. Sarmiento & Scannapieco (2025) estimated a 10-30 Myr limit for Pop III formation, and Fotopoulou et al. (2024) showed that low-metallicity star-forming clouds could be disturbed by stellar feedback and supernovae in less than 10 Myr. Therefore, we annotate 3 and 30 Myr time-scales in Figure 4, to show minimum and maximum time-scales for Pop III formation. In Figure 5, we also estimate the accretion rate onto the protostars that would form, plotted against the mass enclosed, which is computed using the same method as in Figure 4. The accretion rate is estimated using the relation $\dot{M} \sim c_s^3 / G$, where c_s is the sound speed, assuming an ideal gas, and G is the universal gravitational constant. This estimation shows that the accretion rate also increases along with the radiation background, resulting in a more top-heavy IMF for the objects that form in more intense radiative environments.

4 DISCUSSION

4.1 Pop III vs DCBH Formation

Whether the collapsing gas eventually forms a large Pop III cluster or a DCBH depends on the IMF of the objects that form, which is in turn dependent on the accretion rate onto the collapsing cloud. If accretion is sustained at rates between 0.01 and $0.1 M_\odot \text{yr}^{-1}$, then a supermassive star (SMS) would likely form (Inayoshi et al. 2020). The lifetime of such an SMS is expected to be around 1 Myr (Wise et al. 2019). Once the nuclear fuel is exhausted, the SMS would collapse into a DCBH with no supernova, unless the SMS has a mass in a narrow band around $55,000 M_\odot$, in which case a powerful supernova would occur (Chen et al. 2014), leaving behind no remnant. If accretion rates exceed $\sim 0.3 M_\odot \text{yr}^{-1}$, collapse would happen during the helium-burning stage because of a general relativistic instability (Umeda et al. 2016). In each case, the resulting black hole is expected to have a mass of $\sim 10^5 M_\odot$. If accretion rates are not sustained above $\sim 0.01 M_\odot \text{yr}^{-1}$ during the first 10^5 yr (the Kelvin-Helmholtz time-scale), then a star with a mass of order $\sim 100 M_\odot$ would likely form, its mass limited by its own radiative feedback (Haiman 2012).

The accretion rates are dependent on the sound speed, which is in turn dependent on the gas temperature. Therefore, the fate of our clusters can be determined through Figures 4 and 5. In Scenario A, a more bottom-heavy IMF Pop III cluster would form, because less than $100 M_\odot$ will have been accreted after 10^5 years (Figure 4), which is also consistent with the low accretion rates in Figure 5. Scenario B would result in a more top-heavy IMF Pop III cluster, because of the higher accretion rate, although a SMS is still ruled out because the accretion rates remain below the threshold until after

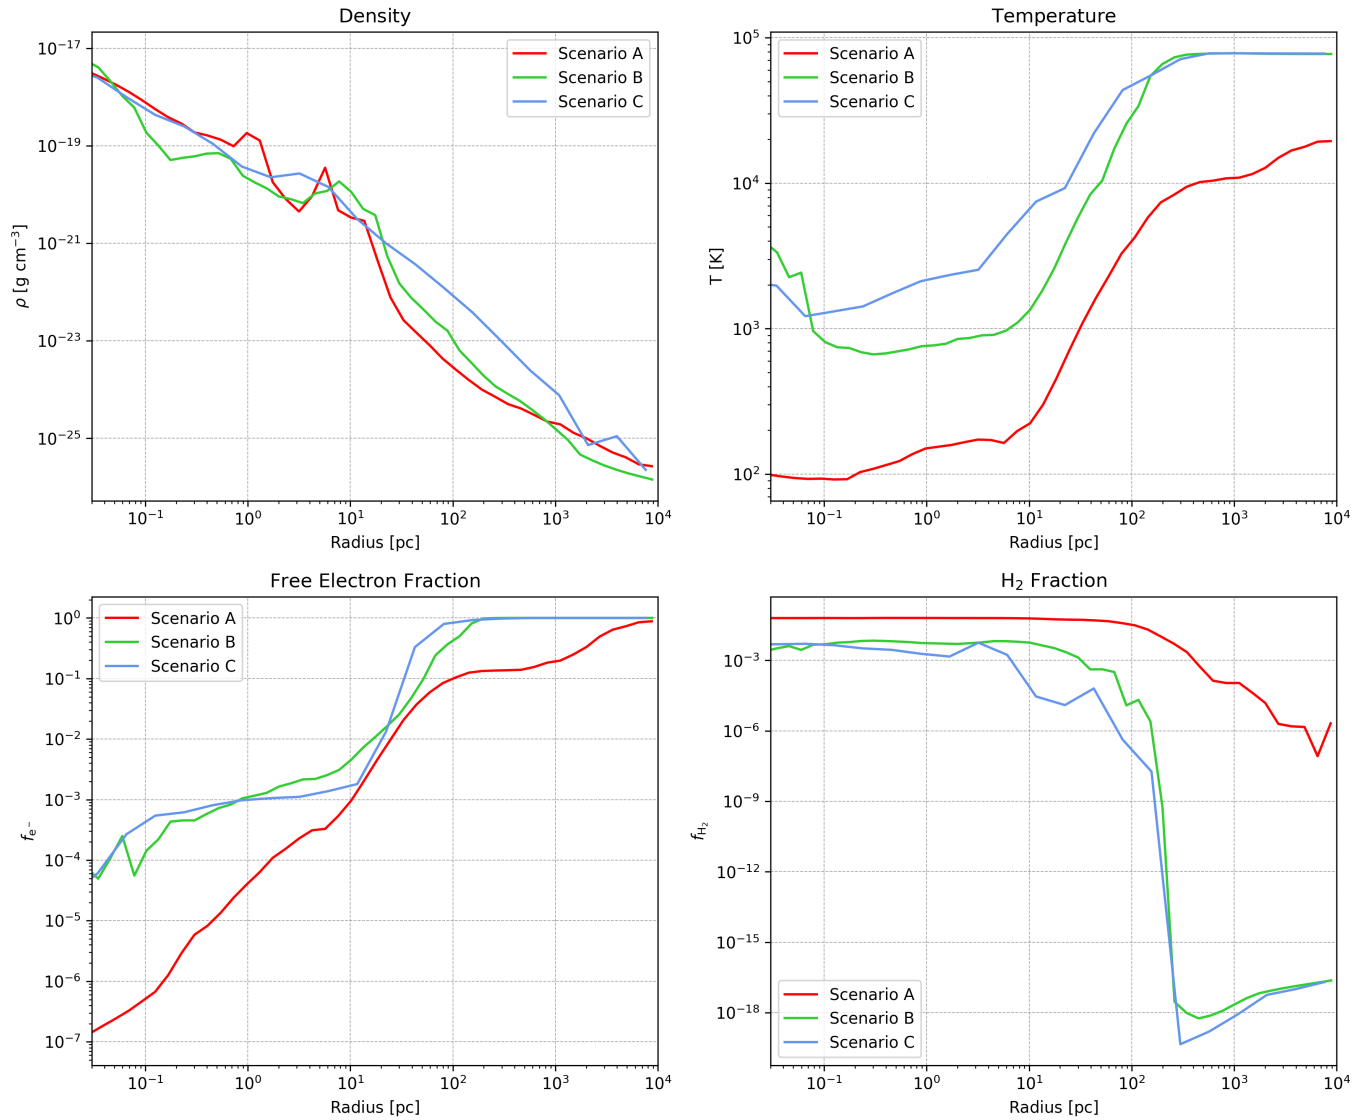

Figure 2. Radial profiles of temperature, density, H_2 fraction, and free-electron fraction, for each scenario, centred on the highest density cell at the moment the highest refinement level is reached (the stopping point for the simulations, after which a rapid runaway gravitational collapse would occur). The free-electron fraction stays elevated as the gas collapses to higher densities, catalysing H_2 formation. The LW flux counteracts this effect.

the Kelvin-Helmholtz time. Only in Scenario C may a DCBH form, because of the sustained high accretion rates.

Thus, we find that for our DM halo of mass $2.23 \times 10^9 M_\odot$ at $z = 12.63$, with an intense background corresponding to a $10^9 M_\odot$ SMBH with the Eddington luminosity 10 kpc away, a DCBH is most likely to form. In Scenarios A and B, corresponding to the same SMBH at respective distances of 1000 and 100 kpc, a large cluster of Pop III stars is instead likely to form, at $z = 24.99$ and 15.46, respectively, with the second cluster having a more top-heavy IMF.

4.2 Detectability by JWST

Maiolino et al. (2024b) observed a Pop III candidate, identified by its He II $\lambda 1640$ emission line, at an estimated distance of 2.5 kpc from the high-redshift galaxy GNz-11 at $z = 10.6$. They estimated a luminosity in this line of order $10^{41} \text{ erg s}^{-1}$. The luminosity of the clusters in our simulations depends on the star formation efficiency

and the IMF of the stars that are formed. Recent work has suggested that star formation efficiency may be elevated at high redshifts, with estimates ranging from around 1% to greater than 10% (Andalman et al. 2025; Venditti et al. 2024; Meidt et al. 2025; Somerville et al. 2025; Ventura et al. 2024; Bovill et al. 2024), with Gentile et al. (2024) even suggesting that star formation efficiencies for Little Red Dots could be 25-50%. Kar et al. (2025) also suggested that star formation efficiency could be a function of halo mass and redshift. We therefore assume a 10% star formation efficiency, and a top heavy IMF (Bromm et al. 2001). We also note that Wasserman et al. (2025) showed that rotating Pop III stars would have enhanced He II $\lambda 1640$ emission, reducing the top-heaviness of the IMF that would be necessary for detection.

Using the same method as Johnson (2010), we compute an expected luminosity of our Pop III clusters in all three of our simulated scenarios. The luminosity emitted by a Pop III cluster in the He II

Figure 3. Density and temperature slices at the moment the highest level of refinement is reached for the lowest (*left*), intermediate (*middle*) and highest (*right*) background radiation fields. In Scenario A (lowest background), the gas cools to the temperature of the CMB because of HD cooling. With the two higher backgrounds (Scenarios B and C), H₂ formation is limited by the LW flux.

$\lambda 1640$ emission line can be approximated as

$$L_{1640} \approx 4 \times 10^{38} \text{ erg s}^{-1} \times \left(\frac{1 - f_{\text{esc}}}{1} \right) \times \left(\frac{f_*}{0.01} \right) \times \left(\frac{f_{\text{coll}}}{0.1} \right) \times \left(\frac{Q_{\text{HeII}}}{5 \times 10^{45} \text{ s}^{-1} M_{\odot}^{-1}} \right) \times \left(\frac{M_{\text{h}}}{10^8 M_{\odot}} \right), \quad (6)$$

where f_{esc} is the photon escape fraction, f_* is the star formation efficiency, Q_{HeII} is the number of He-II ionizing photons ($M_{\odot}^{-1} \text{ s}^{-1}$) in the stars that form, f_{coll} is the fraction of the gas that cools and collapses, and M_{h} is the DM halo mass. The corresponding observed flux is:

$$F_{1640} \approx 10^{-20} \text{ erg s}^{-1} \text{ cm}^{-2} \times \frac{L_{1640}}{10^{40} \text{ erg s}^{-1}} \times \left(\frac{1+z}{10} \right)^{-2} \quad (7)$$

We calculate the gas collapse fraction f_{coll} used in Equation 7 by dividing the gas enclosed (shown in Figure 4) by the gas mass within the virial radius of the DM halo. Using $Q_{\text{HeII}} = 3.8 \times 10^{47} M_{\odot}^{-1} \text{ s}^{-1}$ (based on the top-heavy IMF), an escape fraction of zero, and a star formation efficiency of 10%, values of L_{1640} and F_{1640} are shown in Appendix B for the three different scenarios, at three different times post collapse.

Maiolino et al. (2024b) observed the candidate Pop III cluster near GN-z11 using the *JWST* NIRSpec instrument, in integral field spectroscopy (IFS) mode. They had an exposure time of 10 hours 46 min-

Table 1. Signal-to-noise ratios (SNRs) for three simulated scenarios using *JWST*/NIRSpec. SNRs for the He II $\lambda 1640$ flux are listed for cluster masses corresponding to the enclosed masses with infall times of 3, 10, and 30 Myr shown in Figure 4.

Scenario	Collapse z	SNR (3 Myr)	SNR (10 Myr)	SNR (30 Myr)
A	24.99	0.06	0.18	0.59
B	15.46	1.74	3.39	9.32
C	12.63	3.25*	14.07*	46.89*

*For Scenario C, we show in Section 4.1 that a DCBH is likely to form. This DCBH could be accompanied by a stellar population and/or other DCBHs. The SNRs shown for Scenario C represent the maximum possible stellar contribution.

utes, with the G235M/F170LP grating/filter pair. Using the *JWST* exposure time calculator (Pickering et al. 2016), we calculate the SNRs of our three clusters under the same observing strategy, except for Scenario A at $z = 24.99$, where we instead use the G395H/F290LP grating/filter pair (the emission line at $z = 25$ is redshifted out of the range of the G235M/F170LP pair). We list the signal-to-noise ratios (SNRs) for the fixed slit observing mode instead of the IFS mode, to simplify the calculation; we found that the IFS SNRs were comparable. These SNRs are listed in Table 1. We find that Scenario A is not detectable without the help of significant gravitational lensing. On the other hand, Scenarios B and C could be detectable.

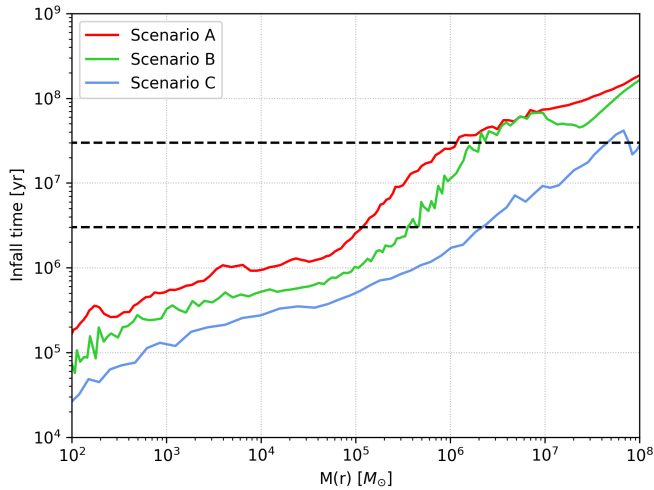

Figure 4. Infall time vs. mass enclosed, for each of the three backgrounds at the moment of collapse, using a similar methodology to [Visbal et al. \(2017\)](#), where infall time is radial distance divided by spherically averaged radial velocity. Cells which had a negative radial velocity relative to the highest density cell were excluded from the calculation, because they correspond to outflowing gas that would not be accreted. The dashed lines represent 3 million and 30 million year time-scales, representing the lifetime of the most massive stars, and the maximum time limit from [Sarmiento & Scannapieco \(2025\)](#), respectively.

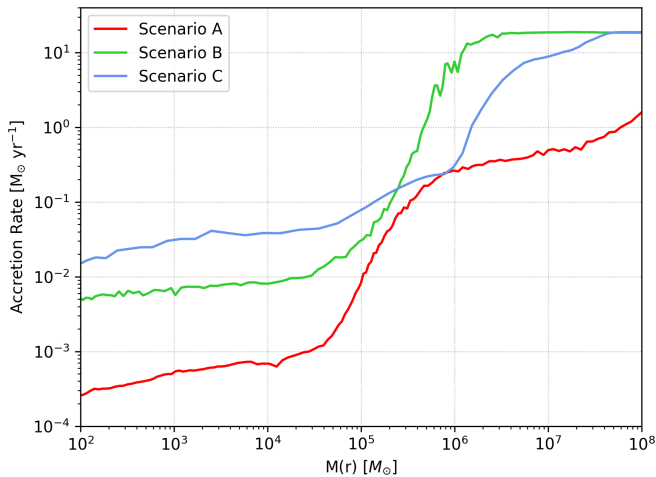

Figure 5. Accretion rate, approximated using the relation $\dot{M} \sim c_s^3/G$, is plotted as a function of mass enclosed. Only in Scenario C are there sustained accretion rates high enough to form a DCBH.

We can make a direct comparison between GNz-11 and our model SMBH, by assuming that GNz-11 hosts a black hole of around $2 \times 10^6 M_\odot$, and accretes at around five times the Eddington rate ([Maiolino et al. 2024a](#)). [Maiolino et al. \(2024b\)](#) estimated that the He II clump was around 2.5 kpc away from GNz-11. Therefore the flux from GNz-11 at the distance of the He II clump would be around 0.16 times the flux in Scenario C, and 16 times the flux in Scenario B. Assuming the mass infalling within 30 Myr is also intermediate between scenarios B and C, at around $\sim 10^7 M_\odot$, and again assuming a star formation efficiency of 10% and an escape fraction of zero, then the expected luminosity of the He II clump would be $\approx 3 \times 10^{41} \text{ erg s}^{-1}$, which is in line with the luminosity that was actually observed.

Therefore, we conclude that Scenarios B and C could be detectable with *JWST*. Scenario A, even assuming a top-heavy IMF, when in fact the cluster would likely have a more bottom-heavy IMF than Scenarios B and C, would only have an SNR of up to 0.59, meaning that it is very unlikely to be detectable with *JWST*. In Scenario B, we conclude that a large, pure Pop III cluster could be detectable with *JWST*'s NIRSpec instrument. In Scenario C, the collapsing gas will form one or more DCBHs, which may be accompanied by a detectable stellar population.

5 CONCLUSIONS

We have presented three-dimensional radiation-hydrodynamics simulations of three scenarios, corresponding to DM haloes exposed to the radiation from an SMBH with a bolometric luminosity of $1.26 \times 10^{47} \text{ erg s}^{-1}$. We ran simulations with background radiation fields of the SMBH at respective distances of 1000, 100, and 10 kpc from our DM halo (Scenarios A, B, and C, respectively), using an isotropic radiation background, calculated using an SED ([Haardt & Madau 2012](#)) that extends from $3 - 10^6 \text{ eV}$. Our main findings are the following:

- The high-energy portion of the SED has a significant effect on the collapsing gas. Compton scattering maintains a high free-electron fraction even as the gas cools and collapses. This high free-electron fraction in turn catalyses H_2 formation, which allows further cooling of the gas through H_2 radiative quadrupole transitions and HD dipole transitions. Moreover, Compton scattering heats the ionized gas to higher temperatures than possible with only an ionizing UV background. This further delays gravitational collapse until the virial temperature exceeds the Compton equilibrium temperature, which allows more gas to be available for Pop III formation. In our simulations, this corresponds to collapse at $z = 24.99, 15.46$ and 12.63 for Scenarios A, B, and C respectively. These effects are not captured by previous work simulating the effect of an ionizing radiative background on Pop III formation (e.g. [Visbal et al. 2017](#); [Kulkarni et al. 2019](#); [Park et al. 2021](#)).

- The level of the radiation background changes the IMF of the objects formed after collapse. Scenario A corresponds to a lower-IMF Pop III cluster, Scenario B to a high-IMF Pop III cluster, and Scenario C to a DCBH, which may be accompanied by a stellar population. [Maiolino et al. \(2024b\)](#) found that the IMF of the stars powering the He II clump near GNz-11 must extend to at least $500 M_\odot$. This is consistent with our simulations, which show that an intense radiation background would increase the IMF of a Pop III cluster.

- We find that Pop III clusters formed near AGN may be detectable in He II $\lambda 1640$ out to $z \sim 15$ using *JWST*'s NIRSpec instrument, in both fixed slit and IFS modes.

DATA AVAILABILITY

All of the simulations presented in this article were run using ENZO v2.6.1 (commit hash 399df69). The source code was modified to add isotropic photoionization, photoheating, and photodissociation rates, and a treatment for Compton scattering off of our background. Initial conditions were generated using MUSIC using the coarse grid seed 27700. The seeds for levels 8 and 9 were 44278, and 66886, respectively. All computational analysis of the snapshots generated was done using yt. The source code for these three programs is publicly available. The ENZO parameter files used, along with the final snapshots, are available upon request from EMF.

APPENDIX A: COMPUTED RATES

In Table A1, we show the isotropic photoionization and photoheating rates for Scenario B. The LW rate for Scenario B was $J_{21} = 5232$. Rates for Scenarios A and C can be computed by multiplying, or dividing, respectively, the given rates by 100.

APPENDIX B: DETECTABILITY CALCULATIONS

The expected luminosities of the clusters, and the fluxes that could be observed by JWST, are listed in Tables B1 and B2, respectively.

This paper has been typeset from a \LaTeX file prepared by the author.

Table B1. He II $\lambda 1640$ luminosities (erg s^{-1}) for the three simulated scenarios, at three characteristic time-scales after runaway gravitational collapse. In comparison, the He II clump from [Maiolino et al. \(2024b\)](#) has an estimated luminosity of $\sim 10^{41} \text{ erg s}^{-1}$.

Scenario	3 Myr	10 Myr	30 Myr
A	1.18×10^{40}	3.55×10^{40}	1.18×10^{41}
B	1.91×10^{41}	3.82×10^{41}	1.15×10^{42}
C	3.20×10^{41}	1.60×10^{42}	8.01×10^{42}

Table B2. Observed He II $\lambda 1640$ fluxes ($\text{erg s}^{-1} \text{ cm}^{-2}$) for the three simulated scenarios using *JWST*/NIRSpec.

Scenario	3 Myr	10 Myr	30 Myr
A	1.75×10^{-21}	7.01×10^{-21}	1.75×10^{-20}
B	7.04×10^{-20}	1.41×10^{-19}	4.23×10^{-19}
C	1.73×10^{-19}	8.66×10^{-19}	4.33×10^{-18}
