ABSTRACT

We present a panchromatic optical–mm characterization of GNz7q, a recently identified X-ray weak, rapidly growing red quasar embedded within a dusty starburst galaxy at $z = 7.1899$, using the full suite

of JWST/NIRCam, NIRSpect, MIRI, and archival NOEMA observations. Our deep NIRSpect/G395M spectroscopy reveals unambiguous broad Balmer emission ($\text{FWHM} = 2221 \pm 20 \text{ km s}^{-1}$), confirming a super-Eddington accreting black hole ($\lambda_{\text{Edd}} = 2.7 \pm 0.4$) with a mass of $\log(M_{\text{BH}}/M_{\odot}) = 7.55 \pm 0.34$, using accretion-rate corrected BH mass estimators. After subtracting the point source, we robustly detect stellar emission from the host galaxy across multiple NIRCam and MIRI filters. Our joint morphological–spectral analysis yields a stellar mass of $\log(M_{*}/M_{\odot}) = 10.5 \pm 0.4$ and an intense star formation rate of $\text{SFR} = 330 \pm 97 M_{\odot} \text{ yr}^{-1}$, confirming the host as a massive, dusty starburst galaxy. We find that GNz7q lies on the local $M_{\text{BH}}\text{--}M_{*}$ relation ($M_{\text{BH}}/M_{*} \simeq 0.001$) and is well positioned to evolve into the locus of massive SDSS quasars with $\log(M_{\text{BH}}/M_{\odot}) \approx 9$ and $M_{*} \approx 10^{11} M_{\odot}$ at $z \sim 6$, owing to its remarkably rapid growth in both the black hole and its host galaxy. This stands in stark contrast to many recently reported JWST AGN populations at similar redshifts, including the little red dots (LRDs), whose weak or undetected star formation makes it difficult for them to grow into the massive galaxies hosting SDSS-like quasars. These results suggest that GNz7q marks a rare, pivotal phase of early BH–galaxy co-evolution, plausibly providing a crucial direct pathway to the supermassive black hole systems within the first billion years of the Universe.

Keywords: AGN; IMBH; BHMF

1. INTRODUCTION

The discovery of luminous quasars at redshift $z \gtrsim 6$ has fundamentally challenged our understanding of the early Universe (e.g., Smith & Bromm 2019; Woods et al. 2019). The existence of supermassive black holes (SMBHs) with masses exceeding $10^9 M_{\odot}$ less than 1 Gyr after the Big Bang (e.g., Fan et al. 2001, 2006; Mortlock et al. 2011; Bañados et al. 2018; Wang et al. 2021a) necessitates specific mechanisms for rapid black hole growth. Theoretical models suggest that these giants grew from either heavy seeds, arising from the direct collapse of massive primordial gas clouds, or light seeds originating in stellar remnants that underwent continuous, super-Eddington accretion (e.g., Volonteri 2012; Inayoshi et al. 2020). In addition, these high- z quasars appear to host ‘overmassive’ BHs (Yue et al. 2024; Stone et al. 2024; Li et al. 2025b), relative to the stellar mass of their host galaxies when compared to the local $M_{\text{BH}} - M_{*}$ relations (Kormendy & Ho 2013; Reines & Volonteri 2015; Greene et al. 2020; Zhuang & Ho 2023).

The launch of JWST has opened a new window into this field, unveiling a previously hidden population of fainter AGNs at high redshifts (e.g., Harikane et al. 2023; Larson et al. 2023; Kokorev et al. 2023; Koccevski et al. 2023; Furtak et al. 2024; Maiolino et al. 2024a,b; Matthee et al. 2024; Lin et al. 2024, 2025; Taylor et al. 2025a,b; Hviding et al. 2025; Fei et al. 2025a). Identified by broad rest-frame optical Balmer lines, these sources enable the study of lower-mass black holes ($M_{\text{BH}} \sim 10^5 - 10^8 M_{\odot}$) in the early Universe. In

contrast to massive, luminous quasars that display mature features (Bosman et al. 2024, 2025), these objects likely represent a nascent phase of black hole growth (Inayoshi 2025; Jeon et al. 2025a).

Many of these lower-luminosity AGNs reside in low-mass galaxies ($\sim 10^8 M_{\odot}$), revealing BH-to-stellar mass ratios (M_{BH}/M_{*}) that deviate more dramatically from the local relationship, with some objects exhibiting values 10 to 100 times higher than the local benchmark (e.g., Izumi et al. 2019; Maiolino et al. 2024a; Chen et al. 2025b; Li et al. 2025a), though this deviation may be less extreme if BH masses are systematically lower by ~ 1 dex as recently suggested (e.g., Greene et al. 2025; Umeda et al. 2025; Asada et al. 2026). The presence of such high M_{BH}/M_{*} ratios may directly support the existence of ‘heavy seeds’ formed via Direct Collapse Black Holes (DCBHs), providing a possible mechanism for the rapid early growth of SMBHs (Pacucci & Loeb 2024; Maiolino et al. 2024a; Jeon et al. 2025b), or implicate more exotic formation channels (e.g., the core collapse of self-interacting dark matter; Jiang et al. 2025) or even primordial BHs (e.g., Bean & Magueijo 2002; Carr & Kühnel 2020; Dayal 2024; Zhang et al. 2025). However, we need to consider that this observed deviation could be partially driven by observational biases, since flux-limited surveys may preferentially detect systems where the central engine outshines the host, artificially skewing samples toward high mass ratios (Li et al. 2025a; Silverman et al. 2025).

Crucially, whether these faint, overmassive sources represent the direct progenitors of the luminous quasars observed at $z \sim 6$ remains an open question. To fully bridge these populations, it is essential to investigate

* Hubble Fellow

the co-evolution of both the BH and the host galaxy, yet significant physical discrepancies exist between the two regimes. Unlike the vigorous starbursts associated with luminous quasar host galaxies (e.g., Walter et al. 2004; Wang et al. 2010, 2013; Decarli et al. 2018; Venemans et al. 2020; Neeleman et al. 2021; Fei et al. 2025b), JWST-discovered AGNs often exhibit generally low star formation activity, characterized by strong upper limits on their rest-frame IR-derived SFRs (Akins et al. 2025; Casey et al. 2025). Furthermore, these sources usually display low Eddington ratios ($\lambda_{\text{Edd}} \approx 0.1$; Harikane et al. 2023; Maiolino et al. 2024b), contrasting with the rapid accretion required to build SMBHs.

This ambiguity is further compounded by systematic uncertainties in deriving BH properties at these epochs. Standard estimators rely on empirical scaling relations calibrated in the local Universe, which may be inapplicable to high- z faint AGNs given their distinct spectral characteristics¹, such as deviant broad emission-line profiles (Rusakov et al. 2025; Kokorev et al. 2025) and complex absorption features (Wang et al. 2025; D’Eugenio et al. 2025). Theoretical frameworks describing these systems introduce additional complexity (Inayoshi & Maiolino 2025; Naidu et al. 2025; Chang et al. 2025); these model dependencies imply uncertainties in BH mass and accretion rates (\dot{M}) of up to ~ 1 dex (Greene et al. 2025). Consequently, to bridge this gap and empirically verify the transition from faint seeds to luminous giants, it is crucial to investigate rare ‘transitional’ sources (Fu et al. 2025), which occupy the intermediate parameter space and offer simultaneous, robust constraints on both the central AGN and the host galaxy. Comparable systematic uncertainties affect the measurement of the host galaxies. The decomposition of the host galaxy is inherently degenerate due to the overwhelming AGN continuum and limitations in Point Spread Function (PSF) subtraction (Mechtley et al. 2012; Marshall et al. 2020). Furthermore, these photometric ambiguities introduce significant scatter in the physical properties derived via Spectral Energy Distribution (SED) fitting (Ding et al. 2023, 2025).

In addition to these systematic uncertainties in the measurements, the characterization of the high-redshift AGNs is currently limited by the survey volume of JWST. While the unprecedented sensitivity of JWST has revolutionized our ability to probe faint, low-mass galaxies ($M_* \lesssim 10^9 M_\odot$) and low-luminosity AGNs into the epoch of reionization, the relatively small field of

view of deep surveys (compared to all-sky surveys, such as SDSS; Atek et al. 2025; Eisenstein et al. 2023; Rieke et al. 2023) restricts the comoving volume sampled. Consequently, the discovery rate of intrinsically rare, massive galaxies ($M_* > 10^{10} M_\odot$) embedded within the massive dark matter halos ($M_{\text{DM}} \gtrsim 10^{12} M_\odot$) at $z > 6$ remains low (de Graaff et al. 2025a). This volume limitation results in a paucity of spectroscopically confirmed massive host galaxies harboring accreting massive BHs, leaving the properties of these systems largely unexplored.

In this work, we present deep and comprehensive follow-up observations of a unique red quasar, GNz7q, from JWST NIRC*am* and MIRI imaging to NIRS*pec* G140M+G395M, MIRI LRS+MRS spectroscopy. Originally identified in the GOODS-North field (Fujimoto et al. 2022), the source has been spectroscopically confirmed at $z = 7.1899$ via HST grism spectroscopy and the detection of [C II] emission with NOEMA. The broadband SED, constrained by NOEMA dust continuum measurements, indicates that the quasar resides within a vigorous starburst host. Notably, the robust mid-infrared detection in Spitzer IRAC and MIPS bands confirms that GNz7q satisfies the canonical photometric selection criteria for red quasars (e.g., Donley et al. 2012). Furthermore, the non-detection in the deep (~ 2 Ms) Chandra X-ray observations implies high column densities, consistent with a Compton-thick highly-accreting system. These properties suggest that GNz7q likely represents a pivotal transition phase from a dusty starburst to an optically luminous quasar (e.g., Sanders et al. 1988; Hopkins et al. 2008), and might evolve into the luminous quasar at $z \sim 6$.

This paper is organized as follows. In Section 2, we present the observations and data reduction procedures. Section 3 describes the methodology used for the model fitting and spectral analysis. In Section 4, we present the derived physical properties of both the AGN and the host galaxy. Finally, we summarize our conclusions in Section 5. Throughout this paper, we assume a flat universe with $\Omega_m = 0.3, \Omega_\Lambda = 0.7$, and $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$. We use magnitudes in the AB system (Oke & Gunn 1983).

2. DATA

2.1. NIRC*am* image

The NIRC*am* imaging data are retrieved from two programs: GO-4762 (PIs: S. Fujimoto & G. Brammer) and the FRESCO survey (GO-1895; Oesch et al. 2023). The source was observed with NIRC*am* F090W, F115W, F182M, F210M, F356W, and F444W filters. The detailed data reduction procedures are consistent with the

¹ Direct BH mass measurements via resolved JWST integral-field kinematics can provide crucial cross-calibration and validation (Juodžbalis et al. 2025).

standard data reduction procedure (e.g., Oesch et al. 2023; Eisenstein et al. 2023; Atek et al. 2025). Here we briefly mention the process.

The reduction of NIRC*am* imaging data commenced with the processing of uncalibrated files using the JWST Science Calibration Pipeline (v12.0.9) and CRDS context file `jwst_1321.pmap`. Beyond standard STScI procedures, we implemented custom steps to mitigate artifacts, including the removal of snowballs, wisps, cosmic rays, persistence, and diffraction spikes, alongside an initial $1/f$ noise correction. Following Stage 2 pipeline processing, we applied a secondary correction for residual $1/f$ noise via sigma-clipping and performed two-dimensional background subtraction using the `sep` package. The data were then co-added through Stage 3 to produce final astrometrically aligned mosaics (referenced to Gaia stars) with pixel scales of 20 mas pix^{-1} for SW bands and 40 mas pix^{-1} for LW bands. The NIRC*am* grism spectrum also confirms the presence of the broad component (Oesch et al. 2023), we prioritize the NIRS*pec* data for our quantitative analysis due to its higher SNR.

2.2. MIRI image

The MIRI imaging data are also retrieved from two programs: F1280W from GO-4762 (PIs: S. Fujimoto & G. Brammer) and F1000W and F2100W from the MEO*W* survey (GO-5407; Leung et al. 2024). The F1280W data were reduced following the standard procedures established by the Dawn JWST Archive (DJA; Valentino et al. 2023) and widely used in public surveys (e.g., PRIMER Dunlop et al. 2021). Specifically, we retrieved the Level-2 products and processed them using the `grizili` software package (Brammer & Matharu 2021; Brammer et al. 2022), adopting the methodology described in detail by Valentino et al. (2023).

For F1000W and F2100W, the data publicly available in September 2025 for the GOODS-N field, jointly with the proprietary MEO*W* data, were reduced with the JWST Rainbow pipeline following the methodology described in Pérez-González et al. (2024). The observations come from PIDs 1181, 1264, 2926, 4762, and 5407, and mosaics were constructed for filters F560W, F770W, F1000W, F1280W, F1800W, and F2100W. The position of GNz7q is only covered at 10, 12.8, and 21 μm . Details about this reduction (jointly with a similar effort in other fields such as GOODS-S, EGS, or COSMOS) will be presented in Pérez-González et al. (in prep.). We briefly describe here the methodology. The JWST Rainbow database uses the official JWST pipeline adding some extra bespoke reduction step to deal with the background homogenization of the MIRI images. For this

paper, the reduction was carried out with JWST version v1.19.41, reference files in `jwst_1413.pmap`. A key component of this workflow is the ‘superbackground’ strategy, in which background maps for individual exposures are constructed using the full set of campaign images, with known sources masked to mitigate bias. This approach yields a highly homogeneous background in terms of both level and noise. Quantitatively, this method reduces the standard deviation of background pixels in individual `cal.fits` files by a factor of ~ 3.5 relative to the standard pipeline, resulting in a sensitivity improvement of 0.8 mag in the final mosaic. See Appendix A in Pérez-González et al. 2024 for further details, see also Östlin et al. 2025 and Alberts et al. 2024 reporting similar improvements in the noise of the final mosaics.

2.3. NIRS*pec* data

The deep spectroscopic follow-up of GNz7q was obtained with JWST/NIRS*pec* as part of the program (PID 4762l PIs: S. Fujimoto & G. Brammer), using the MOS mode with the G395M grating in F290LP filter ($R \sim 1000$) and G140M grating in F140LP filter. We design the NIRS*pec* MSA configurations following a strategy similar to that adopted in the UNCOVER survey (Bezanson et al. 2024; Price et al. 2025), aiming both to secure the full integration on GNz7q and to maximize the multiplexing return of the deep G395M observations. To this end, we implement a two-tiered prioritization scheme distinguishing between (1) extraordinary or otherwise scientifically unique individual sources, and (2) samples of galaxies of broader interest (e.g., statistical sets of $z > 4$ galaxies). Within this framework, the ranking order is set such that high-priority individual sources are placed first, followed by interesting but less extraordinary individual galaxies, and finally sample-based sources with equal priority within a given catalog. This scheme is used in combination with our custom MSA optimization algorithm to maximize slit allocation efficiency. As a result, a total of 241 sources are allocated slits. The on-source integration time for those sources is 7525 s ($\simeq 2.1$ hr). The data were reduced with the `msaexp` pipeline (Brammer 2023) following standard procedures (e.g., Heintz et al. 2025; de Graaff et al. 2025b; Naidu et al. 2025; Valentino et al. 2025).

2.4. MIRI MRS and LRS

GNz7q was observed with the Medium Resolution Spectrograph (MRS; Wells et al. 2015; Argyriou et al. 2023) of the Mid-Infrared Instrument (MIRI; Rieke et al. 2015; Wright et al. 2015, 2023) on GNz7q as part of the

cycle 3 JWST program GO-4762 (PIs: S. Fujimoto & G. Brammer). The observations were performed with the MRS medium band that cover the wavelength ranges of 5.66–6.63 μm , 8.67–10.13 μm , 13.34–15.57 μm , and 20.69–24.48 μm for channels 1, 2, 3, and 4, respectively. We focus on channel 3 that covers the Pa- α emission line at a redshift of 7.2. The total on-source integration time corresponds to 11939 seconds (3.3 hours), distributed in 8 dither positions that combine the positive and negative dither patterns optimized for point-like sources. For each dither position, a total of two integrations with 17 groups each were obtained using the SLOWR1 readout mode.

The MRS observations were processed with version 1.17.1 of the JWST calibration pipeline and context 1322 of the Calibration Reference Data System (CRDS). We followed the standard MRS pipeline procedure (?), with additional customized steps to improve the quality of the final MRS calibrated products (see [Álvarez-Márquez et al. 2023, 2024](#) for details). The final channel 3 cube has a spatial and spectral sampling of 0.2" \times 0.2" \times 2.5 nm ([Law et al. 2023](#)), respectively, and a resolving power of about 2500 ([Labiano et al. 2021](#); [Jones et al. 2023](#)).

We extracted the 1D integrated spectra of GNz7q using a circular aperture with a radius equal to 0.5 arcsec for channel 3 (see [Figure 3](#)), respectively. We also extracted 15 1D background spectra using the same apertures at random positions of the MRS FoV clean of any emission of the source. We combined these spectra to generate the 1D median and standard deviation of the local background for channel 3. The median, which is compatible with zero, was subtracted from the GNz7q spectra with the goal of removing any systematic residual feature left in the MRS calibration process. The standard deviation was assumed to be the 1 σ uncertainty of GNz7q spectra. As GNz7q is considered spatially unresolved on the MRS observations, we implemented an aperture correction to derive the total Pa α spectra of GNz7q. For the selected apertures in channels 3, the aperture-correction factor is 1.59 following the MRS PSF ([Argyriou et al. 2023](#)).

Data reduction and calibration for the MIRI LRS observations are conducted utilizing the standard JWST pipeline in conjunction with the `msaexp` ([Brammer 2023](#)). One-dimensional spectral extraction was performed via the optimal extraction method ([Horne 1986](#)), employing a point-source profile derived from calibration observations of the A1V standard star BD+601753 (Program ID: CAL-6620; [Sloan et al. 2024](#)). The 2D spectrum and the extracted 1D spectrum are presented

in [Figure B.1](#), and the data analysis is presented in [Section 3.2](#).

3. ANALYSIS

3.1. *NIRSpec G395M spectrum & fitting*

We perform the spectral decomposition using GALFITS ([Chen et al. 2025b,a](#); [Li et al. 2025b](#)), a software developed for simultaneous SED, morphological, and spectral analysis, which can also be used to fit the spectra. The spectral fitting methodology implemented in GALFITS is similar to that of established AGN analysis software (e.g., `pyQSOFIT`, `fantasy`; [Guo et al. 2018](#); [Ren et al. 2024](#); [Ilić et al. 2020](#)), principally decomposing the data into host galaxy continuum, AGN continuum, and emission line features. However, given the high luminosity of this source ([Yang et al. 2023](#)), the observed spectrum is dominated by the central AGN. We therefore consider the stellar continuum contribution negligible in the rest-frame optical and exclude it from the fitting process. This approximation is subsequently confirmed by the broadband SED analysis presented in [Section 4.3](#) (see also [Figure 7](#)). Although broadband SED fitting indicates a significant host galaxy contribution within the MIRI filters, its impact in the rest-frame optical remains sub-dominant and is comparable to the local noise floor. To verify this, we performed a spectral decomposition using `pyQSOFIT`, incorporating both AGN and host components. The results are consistent with our primary analysis, confirming that the host galaxy contribution is negligible across the rest-frame optical regime. Consequently, our final spectral model consists of two primary AGN components: a continuum model (comprising a double power-law and an Iron pseudo-continuum), and the emission line models.

The power-law continuum is parameterized by its amplitude (f_0), spectral index (α), and a pivot wavelength (λ_0) fixed at 5000 Å in the rest frame ($f_\lambda = f_0(\lambda/\lambda_0)^{-\alpha}$). For the iron pseudo-continuum, we employ the empirical Fe II template derived from I Zw 1 ([Boroson & Green 1992](#)). The free parameters for this component are amplitude, velocity shift, and broadening velocity width.

The emission line model incorporates the permitted emission lines (H α , H β , H γ , and He II) and the forbidden lines ([O III] $\lambda\lambda$ 4959, 5007 and [N II] $\lambda\lambda$ 6548, 6584), assuming a tied line width across all species. We model the [O III] lines using two distinct components: a primary narrow-core component tracing the systemic velocity, and a secondary, broader, blueshifted component to account for potential gas outflows. During the fit, the flux ratio of the [O III] λ 5007 to λ 4959 doublet components

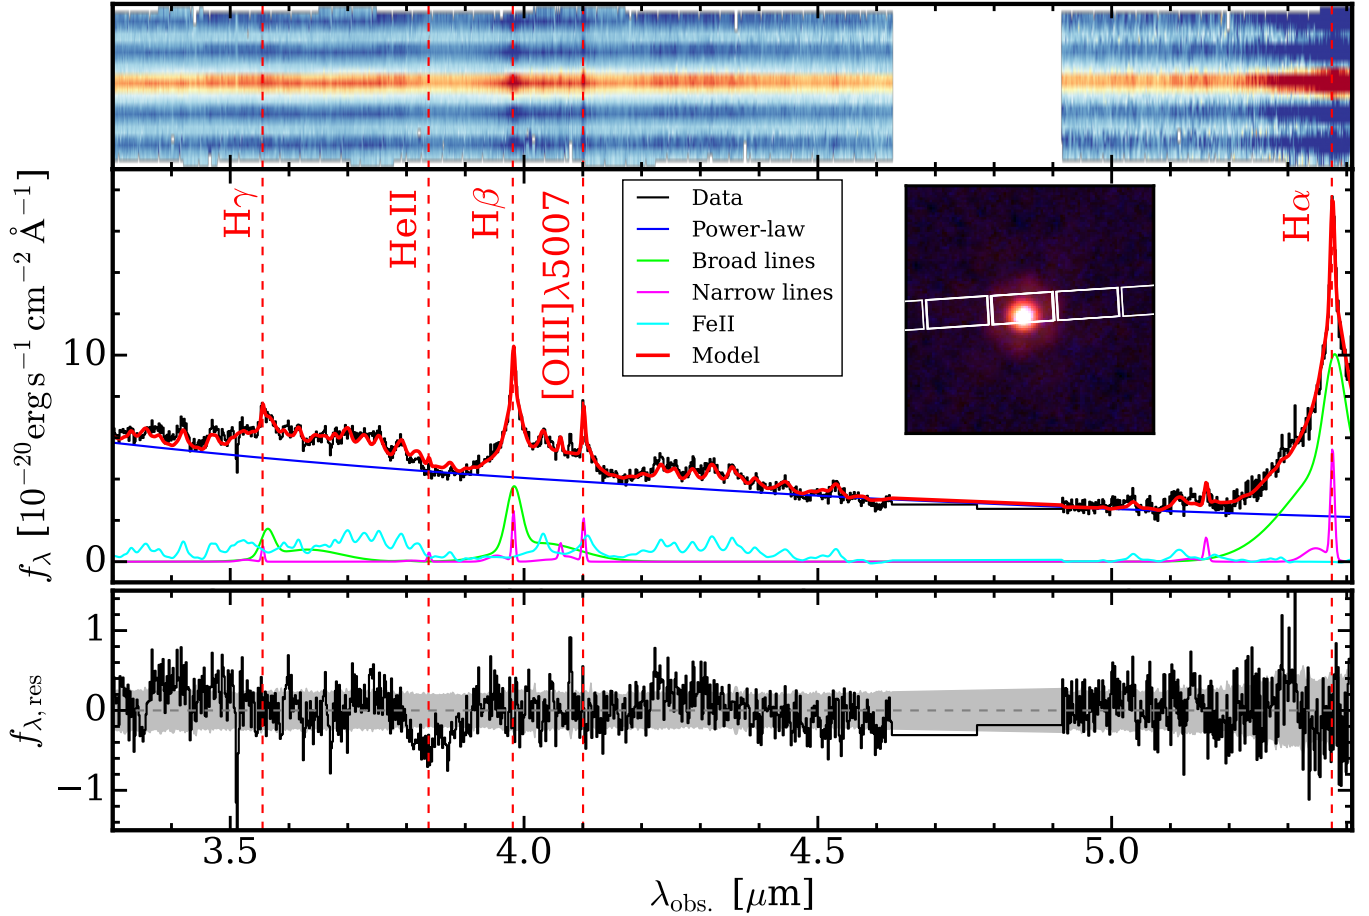

Figure 1. The NIRSpect/MSA spectrum and the best-fit model. Top panel: The 2D spectrum generated from the JWST/NIRSpect observation. Middle panel: The 1D spectrum (black line) extracted from the 2D spectrum and the best-fitting result (red line). The best-fit model consists of several components, including a featureless power-law continuum (blue line), an iron pseudo-continuum (cyan line), the narrow component of emission lines (magenta line), and the broad component of Balmer lines (green line). Bottom panel: The residual between the data and the best-fit model (black line), and the uncertainties (gray dashed region).

is held fixed at its theoretical value of 2.98 (Storey & Zeppen 2000). The line ratio for the [N II] $\lambda\lambda 6548, 6584$ doublets is also fixed to its theoretical value of 2.94.

The decomposed [O III] profile is then used to impose a set of physical constraints on the other emission lines. The profile of the [O III] lines is adopted as the template for all narrow-line components, i.e., the systemic velocity, the line width, and the line ratio between core and outflow component, are fixed when fitting the other forbidden lines and the narrow component of the Balmer lines. We adopted the [O III] doublet as the narrow-line template, as it is a standard tracer and represents the strongest, least-blended forbidden lines in our spectrum. Although the [S II] doublet is another common choice, it falls outside the wavelength coverage of our data and is therefore not used in our fitting. We characterize the broad component of the Balmer lines using two distinct Gaussian components. This double-Gaussian model is

necessary to characterize the shape of the spectrum. We will explain it in the next section and discuss the potential origin of the line profile in Section 4.1. To mitigate the degeneracy between the broad Balmer line profiles and the Iron pseudo-continuum, the kinematic parameters (i.e., line width and velocity center) of each broad component are tied to be the same across the H α , H β , and H γ lines.

Using this model, we perform the fitting using GALFITs with the `multi` task. This routine executes the fitting algorithm multiple times independently. For each iteration, a new set of initial parameters is randomly sampled from the pre-defined, physically allowed parameter space. The solution from this ensemble of fits that yields the global minimum reduced chi-squared (χ^2_{ν}) is then adopted as our final best-fit.

The results of our spectral decomposition are presented in Figure 1. The composite model provides an ex-

Figure 2. Zoom-in view of the $H\beta$ and $H\gamma$ emission lines. The black line shows the observational data after subtracting the global continuum (power-law and Iron Pseudo-continuum). The best-fit model for the emission line is shown in red. Individual components are color-coded, narrow emission is shown as the green line and the emission from the broad line region is shown as blue dashed lines. The two components for the broad emission line are denoted as the blue-dashed and blue-dotted (rBLR) lines, respectively. This redshifted component has been observed in some local quasars, in particular, quasars with high Eddington ratio (Sulentic et al. 2002; Marziani et al. 2009).

cellent representation of the observed rest-optical spectrum. All significant spectral features, including the various emission lines and the underlying Iron pseudo-continuum, are well-reproduced. The quality of the fit is further demonstrated by the residual spectrum (bottom panel in Figure 1), which shows no significant structured features and remains almost entirely within the 1σ flux uncertainties.

The best-fit result reveals that the broad Balmer lines can be well-characterized by two components, including a narrower component from the broad line region (BLR), whose velocity center is consistent with the systemic velocity of the narrow-line region, and a secondary redshifted component (redshifted-BLR, dubbed as rBLR; $\Delta v \approx 3600 \text{ km s}^{-1}$) that has a much broader line width ($\text{FWHM} \approx 11000 \text{ km s}^{-1}$), which have been observed in quasars at lower redshifts (e.g., Sulentic et al. 2002; Marziani et al. 2009). The origin of this redshifted, extremely broad component is still under debate, including the possibility of inflowing gas feeding the central BH growth, or a tidal disruption event (Li et al. 2022). We will discuss the reason for this redshifted broad component in a separate paper (Fujimoto et al. in prep.). This two-component structure is required to fit both the $H\beta$

and $H\gamma$ lines (Figure 2), and we further evaluate the necessity of this component in Section A. While the same model is applied to $H\alpha$, the constraints on its redshifted component are less clear, as the far red wing extends beyond the spectrum’s wavelength coverage.

3.2. MIRI LRS & MRS

The MIRI LRS 1D spectrum was modeled using a methodology consistent with our analysis of the NIR-Spec G395M data, employing a model comprised of a continuum and Gaussian emission lines. A diverse suite of emission features was identified, including He I, O I, and the Paschen series. To isolate the continuum, we performed a preliminary fit using a single power-law after masking these emission regions. As the stellar and dust torus components are not negligible in the observed wavelength regime (see Section 4.3), we model the underlying continuum using a dual power-law formulation. In this framework, the first component characterizes the primary emission from the central engine, while the second accounts for the combined contributions from the host galaxy’s stellar population and the thermal emission from the dust torus.

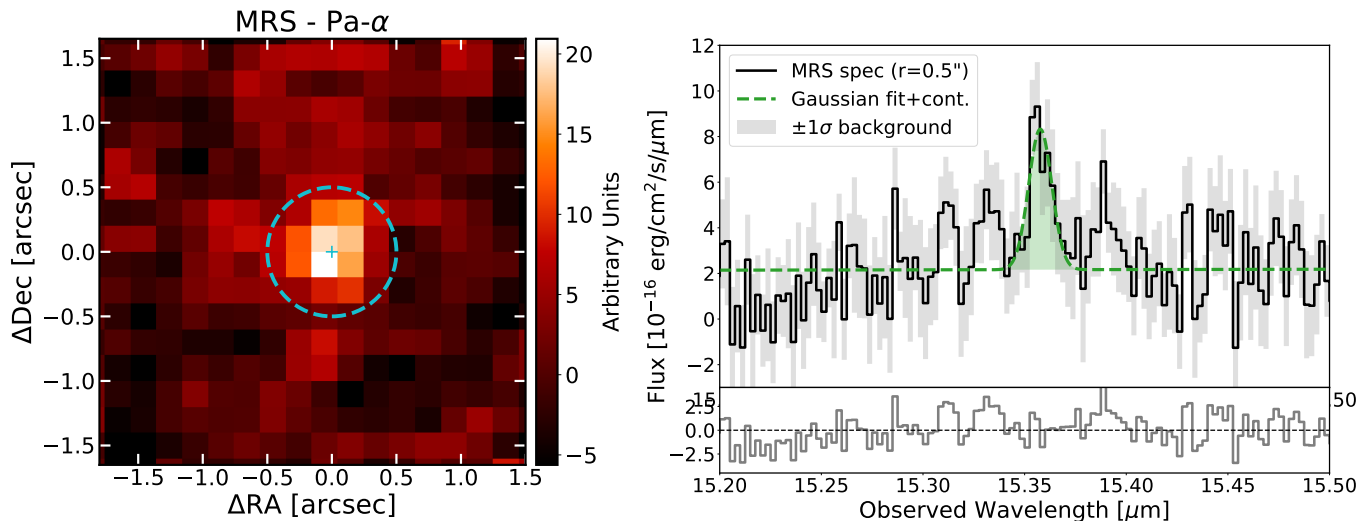

Figure 3. *Left:* The line intensity map generated from the MIRI MRS data around the Pa α emission, with a bandwidth of 1000 km s^{-1} . The lightblue cross in the panel presents the locus of the quasar, and the dashed circle represents an aperture with a radius of $0''.5$. *Right:* Spectrum extracted from the central $0''.5$ aperture of the MIRI observation. Upper panel: The observed flux (solid black line) and associated error (grey shaded region), compared against the best-fit continuum and emission model (green line). Lower panel: The residuals derived from subtracting the model from the observed data.

Subsequently, we model the identified emission features using the continuum-subtracted spectrum. Due to the limited spectral resolution of the MIRI LRS instrument (Kendrew et al. 2015), a detailed decomposition into narrow and broad components is generally omitted in favor of single Gaussian profiles to characterize line morphologies. An exception was made for the H α complex, which is modeled with a double Gaussian profile utilizing empirical constraints derived from our NIRSpec observations. Parameter optimization was conducted via the `lmfit` Python package (Newville et al. 2014). To maintain maximal flexibility amidst the instrument’s resolution limits, we allow the centroid, width, and amplitude of each line to vary independently rather than imposing tied kinematic constraints. This multi-stage approach culminated in a global fit of the MIRI LRS spectrum, employing a composite model of a continuum and Gaussian emission lines whose parameters are initialized from the results of the isolated fits. The final spectral decomposition is illustrated in Figure B.1, with the derived physical parameters shown in Table 2.

Our spectral decomposition reveals that emission features at shorter rest-frame wavelengths, specifically HeI λ 7281, HeI λ 7816, and OI λ 8446, exhibit marginally broader profiles relative to the Paschen series. However, we cannot definitively exclude the influence of instrumental broadening on these observed widths. The MIRI LRS resolving power is lower at the blue end of the spectrum ($R \sim 40$ at $5\mu\text{m}$) compared to the red end ($R \sim 160$ at $10\mu\text{m}$). Consequently, the current spec-

tral resolution precludes a detailed kinematic analysis of these rest-frame near-infrared line profiles.

For the MIRI MRS data, we perform a one-component Gaussian function to characterize the Pa α emission line profiles, with a linear function to fit the background (see Figure 3). The final uncertainties in the fit parameters, such as FWHM, flux, and redshift, were obtained as the standard deviation of all the individual measurements of 1000 bootstrapped spectra after adding a random Gaussian noise equal to the RMS to the original spectrum. The integrated Pa α flux is $(8.8 \pm 2.2) \times 10^{-18} \text{ erg s}^{-1} \text{ cm}^{-2}$ with an intrinsic FWHM of $230 \pm 100 \text{ km s}^{-1}$. The redshift of the Pa α line is 7.1881 ± 0.0009 compatible with the one obtained from NIRSpec spectroscopy (See Table 2)

3.3. SED & Morphological fitting

We perform a simultaneous AGN-host galaxy decomposition and SED fitting using GALFITs to study the host galaxy properties for GNz7q. The software employs a forward modeling approach to simultaneously characterize heterogeneous imaging data, accommodating different instruments, filters, and sensitivities (Li et al. in prep.). The methodology is identical to the procedure established in recent work (Li et al. 2025b; Chen et al. 2025b,a), which already successfully decomposes the AGN and galaxy component for high- z AGNs. As the detailed setup and fitting process are fully described in Li et al. (2025b), we here provide a brief overview of the setup for reference.

Table 1. Properties of GNz7q

NOTE—Derived physical properties of rest-frame near-infrared emission lines from the MIRI spectra. Due to the instrumental broadening and limited spectral resolution, intrinsic line widths are omitted. All non-detections are reported as 2 σ upper limits. Given the poor spectral resolution of the MIRI LRS, no FWHM of those emission lines is shown.

We firstly construct the empirical PSFs for NIRCcam and MIRI images using the field stars (Zhuang & Ho 2023; Li et al. 2025b), which gives the best description for individual stars compared to the relatively sharper PSF generated from the WebbPSF (Yue et al. 2024). The empirical PSF is then used for characterizing the unresolved nuclear emission from the quasar. For its nuclear SED, we adopt a non-parametric approach, treating the luminosity in each photometric band as an independent, free parameter.

This PSF is also used for the host galaxy characterization. The host galaxy component is defined by a simultaneous fit to its morphological and spectral energy distribution (SED) properties. The morphology is parameterized by a single Sérsic profile, which is defined by its centroid, Sérsic index (n), effective radius (R_e), axis ratio (q), and position angle (θ). The host’s stellar SED is modeled via population synthesis assuming a Kroupa (2001) initial mass function. We adopt a non-parametric star formation history (SFH), a choice motivated by the complex, bursty SFHs recently revealed in high- z galaxies by JWST (Wang et al. 2024a; Wright et al. 2024). The free parameters of this stellar population model include the total stellar mass (M_*), the star formation rate (SFR) within discrete temporal bins, the stellar metallicity (Z), and the V-band dust extinction (A_V), for which we assume a Calzetti et al. (2000) attenuation law. We made a simple assumption of energy balance that the FIR energy comes from the stellar

light attenuation, and therefore, implementing the FIR constraints from the JCMT and NOEMA observations (Fujimoto et al. 2022).

To ensure robust convergence and avoid unphysical solutions, particularly in datasets with limited photometric coverage, the fitting process incorporates several priors. These include constraints from established mass-size relations, mass-dust extinction, and mass-metallicity relations, in addition to an SFH prior (Allen et al. 2025; Maheson et al. 2024; Nakajima et al. 2023).

We perform the fitting process using the nested-sampling algorithm (Skilling 2004). We initiated the decomposition by fitting the multi-band imaging with only a pure PSF component. This model proved insufficient, as the residual images clearly revealed a significant, extended component spatially offset from the nucleus. Motivated by this, we tested a two-component model comprising a PSF and a Sérsic component, allowing their centers to be fit independently. This model, which converged on the ~ 2 kpc offset, resulted in a substantially lower BIC, confirming the spatial misalignment between the quasar and this extended host. Finally, we tested a more complex, three-component model to determine if a host component also exists co-spatially with the nucleus. This final model includes a PSF, a Sérsic component co-centered with the PSF, and an offset Sérsic component. This three-component configuration yielded the global minimum BIC, indicating it is the statistically preferred description.

While our primary morphological and spectral analysis utilized GALFITs, we employed cigale (Boquien et al. 2019) as an independent consistency check to validate the derived parameters. The detailed SED fitting process and the setup will be shown in Section 4.3.

3.4. Dust Extinction

Fujimoto et al. (2022) characterized GNz7q as a high-redshift red quasar hosted by a dusty starburst, indicating that the observed emission from both the nuclear and stellar components is strongly suppressed by dust. With the new NIRSPEC observations, we therefore quantify the dust attenuation (A_V). This derived extinction is subsequently applied to infer the intrinsic black hole mass and the bolometric luminosity.

In the same manner as other high- z AGNs studies (e.g., Harikane et al. 2023), we estimate the dust attenuation for the quasar component via the Balmer decrement of the narrow emission lines (including the core component and the outflowing component; Table 1). Adopting a typical dust extinction law and an intrinsic, dust-free narrow-line ratio of $f_{H\alpha}/f_{H\beta} = 2.86$ (Calzetti et al. 2000; Osterbrock 1989), the observed ratio of

$3.03_{-0.07}^{+0.08}$ yields an extinction of $A_V = 0.21_{-0.08}^{+0.09}$ mag, following the method proposed in Domínguez et al. (2013) and Momcheva et al. (2013).

To validate our extinction estimate, we performed an independent estimation based on continuum fitting. We modeled the observed rest-frame UV-to-optical SED using a composite quasar template (Selsing et al. 2016) reddened by a standard dust extinction law (Calzetti et al. 2000), treating the A_V as a free parameter. The resulting A_V is consistent with the value derived from the Balmer decrement of the narrow emission line, while it is different from that obtained from the Balmer decrement derived from the broad emission line ($A_V = 1.9$, assuming an intrinsic ratio of 3.06, which is a common value for local AGN; Dong et al. 2008). However, caution is warranted as the high gas densities characteristic of the BLR deviate from standard Case B recombination assumptions. Consequently, the elevated A_V derived from broad lines likely caused by the collisional excitation rather than the dust attenuation (Son et al. 2025; Yan et al. 2025).

While Paschen-to-Balmer line ratios can offer an independent estimation for dust attenuation (Reddy et al. 2023), the application in this analysis is severely limited by the spectral resolution. Specifically, the low spectral resolution of MIRI LRS precludes the decomposition of Pa β and Pa γ into distinct broad (AGN) and narrow (host) kinematic components, a challenge further compounded by the blending of Pa γ with HeI, $\lambda 10830$. In contrast, the MIRI MRS data recover only the narrow Pa α component attributed to the host galaxy. Consequently, deriving a robust A_V from these inconsistent spectral components is non-trivial. Although the observed Pa α /Pa β flux ratio is consistent with measurements of the broad line region in high- z quasars (Bosman et al. 2024, 2025), we caution that this agreement may be fortuitous given the mixing of physical origins. Definitive constraints on the extinction will require deeper, high-resolution spectroscopy capable of resolving the underlying kinematic substructure.

The A_V of the AGN can also be constrained by photometrically comparing the rest-frame UV-optical SED shape of GNz7q with standard quasar templates (Kato et al. 2020; Selsing et al. 2016; Yang et al. 2021). We also employed this approach to estimate the intrinsic dust reddening. We note that, while the shape of the rest-frame optical continuum of GNz7q is similar to that of typical high- z quasars, the rest-frame UV continuum exhibits a divergent slope distinct from the standard population. This spectral discrepancy suggests a non-standard extinction curve for the central AGN, which cannot be well modeled with a typical extinction curve,

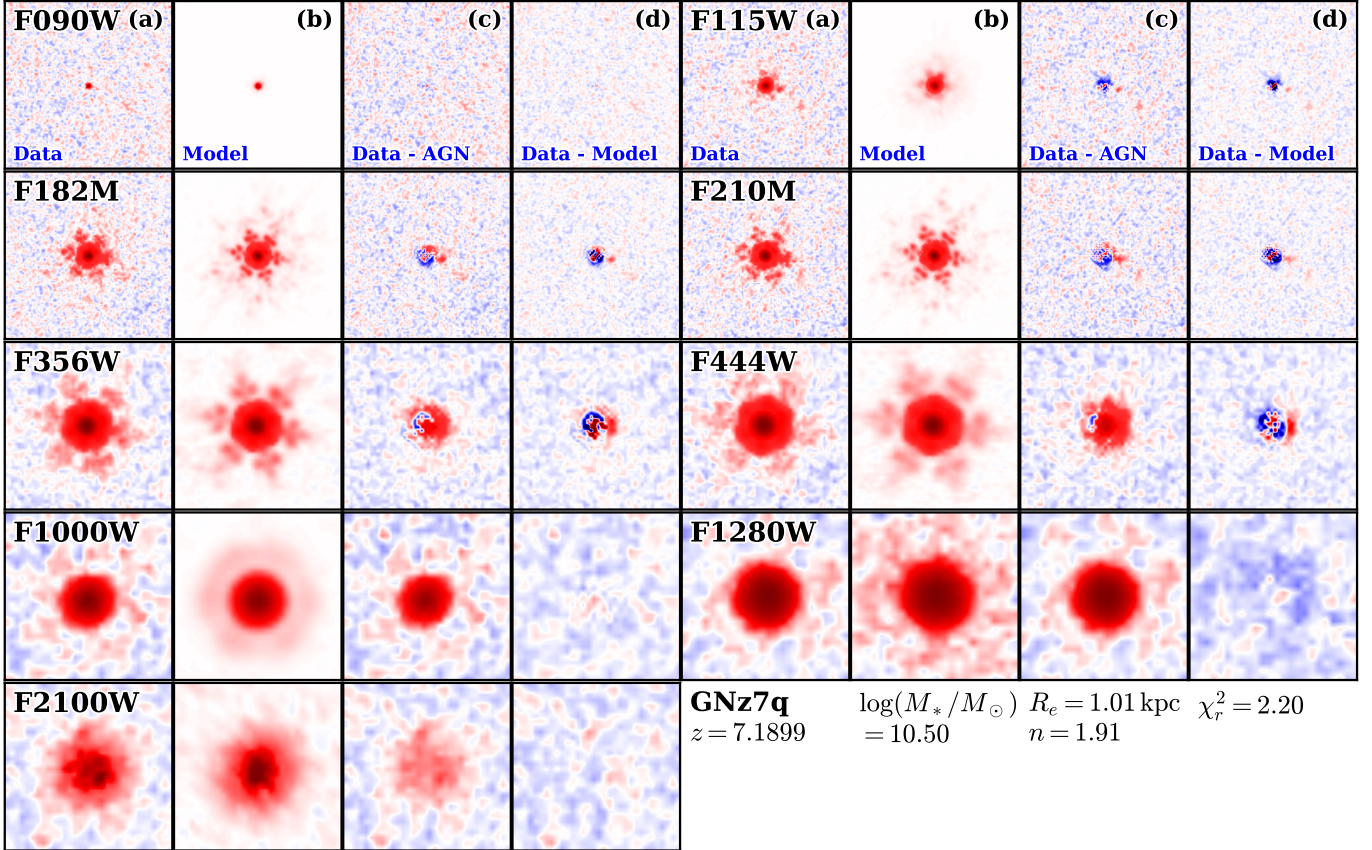

Figure 4. Multi-band AGN-host decomposition for GNz7q. From left to right, the panels display: (a) the original JWST image; (b) the best-fit model; (c) the image of the host galaxy component after Point Spread Function (PSF) subtraction; and (d) the final residual map.

(e.g., Calzetti et al. 2000; Calzetti 2001; Gordon et al. 2003). Such properties have been observed in other high- z systems (Gallerani et al. 2010; Sanders et al. 2025), which may be attributable to specific dust formation mechanisms in quasars (Maiolino et al. 2004; Di Mascia et al. 2021). A comprehensive analysis of this anomalous extinction curve is beyond the scope of the current work and will be presented in a separate paper (Fei et al. in prep.). Consequently, we adopt the value derived from the narrow emission lines, $A_V = 0.21^{+0.09}_{-0.08}$, as the fiducial extinction parameter for the subsequent analyses. This is the most conservative value in terms of the bolometric luminosity and BH mass estimate.

4. RESULTS & DISCUSSION

4.1. BH properties

We then estimate the black hole (BH) properties using the parameters derived from the best-fit model for the spectrum. In particular, the M_{BH} of an AGN is calculated using the virial estimator:

$$M_{\text{BH}} = f_{\text{BLR}} \frac{R_{\text{BLR}} \Delta V^2}{G}, \quad (1)$$

where G is the gravitational constant, R_{BLR} is the radius of the broad line region (BLR), and f_{BLR} is the virial factor, a dimensionless coefficient that accounts for the unknown geometry, kinematics, and inclination angle of the BLR. The velocity, ΔV , is proxied using the width of the broad emission line (e.g., FWHM). The measurement of R_{BLR} is conducted by reverberation mapping (RM), which measures the time lag between variations in the continuum flux and the subsequent response of the broad emission lines. We adopt a virial factor of $f_{\text{BLR}} = 4.16$, based on the reverberation mapping of SDSS quasars (Shen et al. 2024), assuming that the BLR geometry of GNz7q is consistent with that of its low-redshift analogs. These RM studies have demonstrated a robust correlation between the BLR size (R_{BLR}) and the AGN’s luminosity. The luminosity is typically quantified by either the 5100 Å monochromatic luminosity (L_{5100}) or the broad line luminosity (L_{BLR}). This established Radius-Luminosity relationship is foundational, and it allows for the calibration of single-epoch virial mass estimators. These empirical formulae, which are benchmarked against AGN samples in the local Universe (e.g., Greene & Ho 2005; Vestergaard & Peterson

2006; Reines & Volonteri 2015), enable the estimation of M_{BH} using the line widths and luminosities measured from a single spectrum even for high- z AGNs. However, we caution that recent interferometric studies of luminous high- z quasars suggest that the BLRs of super-Eddington accretors may be systematically larger than those of local quasars, potentially leading to an overestimation of M_{BH} by ~ 0.3 dex (e.g., Abuter et al. 2024).

Initially identified as a Compton-thick, super-Eddington candidate exhibiting significant X-ray faintness (Fujimoto et al. 2022), this source suggests that BH mass estimators derived from local, lower-accretion AGNs may require modification. The reverberation mapping analyses have revealed that the canonical luminosity-size relation, which is calibrated on local AGNs with moderate accretion rates, is not universally applicable (Du et al. 2015, 2016, 2018) and is regulated by the accretion rate. This is caused by the theoretical prediction that the canonical BLR framework from the photo-ionizing model, $R_{\text{BLR}} \propto L_{\text{ion}}^{1/2}$, where R_{BLR} is the size of the BLR and L_{ion} is the luminosity of the ionizing source, requires specific structure of the BLR, which may be modified when the accretion rate exceeds the Eddington ratio (Wang et al. 2014; Czerny et al. 2019). Studies targeting massive BHs with higher accretion rates in the local Universe have found that these objects exhibit $\text{H}\beta$ time lags that are systematically shorter by factors of ~ 2 – 8 than predicted by the canonical relation for given luminosities (Du et al. 2015, 2016, 2018). The statistical analysis of these local AGNs confirmed that the magnitude of this lag shortening strongly correlates with the accretion rate (Du et al. 2016, 2018). A physical explanation for this discrepancy is the self-shadowing effect of a slim accretion disk, which is expected to form in super-Eddington regimes (e.g., Wang et al. 2014). In this model, the inner part of the disk becomes geometrically thick due to intense radiation pressure. This inflated disk then anisotropically shields the BLR from ionizing photons, causing the $\text{H}\beta$ ionization front to shrink. Given this established dependency, applying the canonical $R_{\text{BLR}} - L_{5100}$ relation to a high-accretion-rate object would result in an erroneous R_{BLR} and, consequently, an incorrect BH mass (Abuter et al. 2024).

To estimate the BH mass, we first determine the BLR size using Equation (6) of Du et al. (2015) with the $\text{H}\beta$ based empirical relationship, which explicitly accounts for the Eddington ratio. We then calculate the BH mass using this BLR size, a typical virial parameter, and an assumed high accretion rate of $\dot{M} \geq 3$ (Fujimoto et al. 2022). This procedure, incorporating the dust extinction correction of $A_V = 0.21$, yields a mass for GNz7q

of $\log(M_{\text{BH}}/M_{\odot}) = 7.55 \pm 0.34$. The uncertainty is mainly contributed by the systematic uncertainty embedded within the calibrator, which is 0.31 dex (Shen et al. 2024). This value is approximately two orders of magnitude lower than typical quasars at $z \gtrsim 6$ (Fan et al. 2023) and is consistent with the high-mass end of the BH mass function (BHMF) for the faint JWST-detected AGN population (Matthee et al. 2024; Taylor et al. 2025a).

To validate our results, we cross-check the BH mass using two independent empirical relations. First, applying the continuum-based estimator (Equation 5 of Du et al. 2018) yields $\log(M_{\text{BH}}/M_{\odot}) = 7.60 \pm 0.40$. Second, using the Fe II-based size-luminosity relation (Du & Wang 2019; Pan et al. 2025) results in $\log(M_{\text{BH}}/M_{\odot}) = 7.55 \pm 0.40$. Both values are in agreement with our primary Eddington-ratio corrected $\text{H}\beta$ estimate. This consistency indicates that the scaling between the BLR and continuum luminosities follows the empirical relationships established for the local Universe (Greene & Ho 2005), suggesting that GNz7q possesses a BLR structure comparable to typical low-redshift AGNs (Bosman et al. 2024, 2025). We note that estimates using traditional scaling relations (excluding Eddington-ratio corrections, e.g., Greene & Ho 2005) also fall within the consistent range of $10^{7.5}$ – $10^{7.8} M_{\odot}$, using different BH mass estimators. Given that the ionizing accretion disk is spatially compact relative to the BLR radius, we adopt the Eddington-ratio corrected, $\text{H}\beta$ -based determination as our fiducial mass.

The above-mentioned BH mass estimate already considers the effect of the dust extinction. Given the relatively low A_V in the rest-frame optical ($A_V = 0.21_{-0.09}^{+0.08}$), the corrected broad $\text{H}\beta$ flux of $f_{\text{H}\beta, \text{BLR}} = 1039 \pm 30 \times 10^{-20} \text{ erg s}^{-1} \text{ cm}^{-2}$. Due to the shallow dependence of the virial mass on luminosity ($M_{\text{BH}} \propto L^{0.5}$), this correction corresponds to a marginal increase in the BH mass of approximately 5% (~ 0.02 dex), which falls well within the systematic uncertainties.

We derive a bolometric luminosity of $L_{\text{bol}} = (1.50 \pm 0.20) \times 10^{46} \text{ erg s}^{-1}$ from the best-fit SED. Taking uncertainties into account, this is in good agreement with the value of $(1.0 \pm 0.3) \times 10^{46} \text{ erg s}^{-1}$ inferred from the 5100 Å monochromatic luminosity using the bolometric correction of Kaspi et al. (2000). The Eddington ratio (λ_{Edd}) was then calculated with Trakhtenbrot et al. (2011):

$$\lambda_{\text{Edd}} = \frac{L_{\text{bol}}/\text{erg s}^{-1}}{1.5 \times 10^{38} M_{\text{BH}}/M_{\odot}}, \quad (2)$$

where $1.5 \times 10^{38} M_{\text{BH}}/M_{\odot}$ is the Eddington luminosity of the BH. Based on the derived luminosity and the fiducial

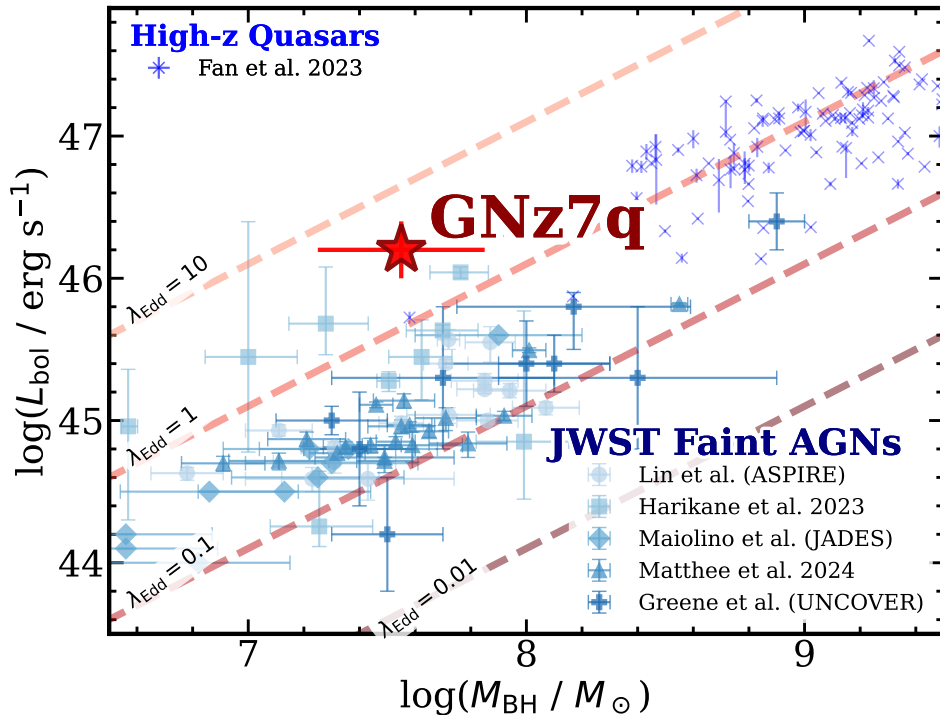

Figure 5. BH mass vs. bolometric luminosity of GNz7q and other AGNs at $z > 4$, including the quasars discovered by ground-based facilities (Shen et al. 2019; Reed et al. 2019; Yang et al. 2021; Farina et al. 2022) and the JWST discovered faint AGNs (Matthee et al. 2024; Harikane et al. 2023; Maiolino et al. 2024b; Lin et al. 2024; Greene et al. 2024).

BH mass, the source is characterized by a highly super-Eddington ratio of $\lambda_{\text{Edd}} = 2.7 \pm 0.4$.

Evidence for super-Eddington accretion is further strengthened by the identification of the OI λ 8446 emission (Figure B.1; Table 2). As detailed by Inayoshi et al. (2022), this low-ionization feature primarily originates from a dense gaseous disk ($0.1 \lesssim r \lesssim 1\text{pc}$) close to the central massive BH. Such broad [O I] lines powered by AGNs were also discovered in recent faint AGNs (LRDs) discovered by JWST (Tripodi et al. 2025; Kokorev et al. 2025; Sun et al. 2026)

In Figure 5, we show the BH mass and bolometric luminosity relation of GNz7q by plotting its location on the $L_{\text{bol}} - M_{\text{BH}}$ plane alongside other AGNs in the early Universe ($z > 4$). For comparison, we also show highly luminous quasars so far discovered with ground-based facilities and the emerging population of faint AGNs recently identified with JWST, at similar redshifts with GNz7q ($z > 4$) compiled from the literature (Shen et al. 2019; Yang et al. 2021; Farina et al. 2022; Matthee et al. 2024; Harikane et al. 2023; Maiolino et al. 2024b; Lin et al. 2024; Greene et al. 2024). Our analysis demonstrates that GNz7q is placed in the highest λ_{Edd} regime among the quasar/AGN populations so far identified at $z > 4$. This significantly elevated accretion rate implies that the source is undergoing a phase of rapid mass assembly, consistent with the evolutionary pathway re-

quired to form the most massive SMBHs observed at $z \sim 6$.

4.2. X-ray faintness

The nature of GNz7q as a candidate for a Compton-thick quasar at $z > 7$ was initially suggested by its non-detection in one of the deepest Chandra X-ray surveys, despite its high luminosity in the infrared (Fujimoto et al. 2022). This phenomenon of X-ray faintness has recently become a recurring theme in JWST observations, particularly among the emerging population of LRDs and faint broad-line AGNs (e.g., Maiolino et al. 2025). Motivated by this context, we revisit the X-ray properties of GNz7q utilizing our updated bolometric luminosity (L_{bol}) estimate. Adopting an intrinsic X-ray photon index of $\Gamma = 2.0$ that follows the relation $N(E) \propto E^{-\Gamma}$, where E is the energy of photons and $N(E)$ represents the X-ray spectra, we derive an upper limit of $L_{2-10\text{keV}} < 2.9 \times 10^{42} \text{ erg s}^{-1}$. Figure 6 compares GNz7q against the empirical relation between the bolometric to X-ray luminosity ratio ($k_{\text{bol}} \equiv L_{\text{bol}}/L_{2-10\text{keV}}$) and bolometric luminosities Duras et al. (2020). We also present other high- z AGNs as the comparison sample (e.g., Wang et al. 2021b; Maiolino et al. 2025). We find that GNz7q deviates from standard quasar scaling relations at a confidence level of $> 5\sigma$. While this suppression generally mirrors the X-ray faint AGN population

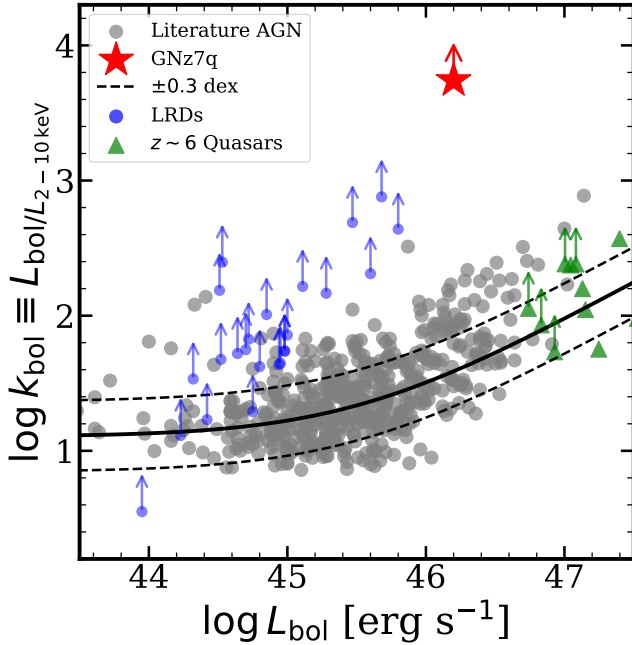

Figure 6. Unique X-ray faintness of GNz7q, compared to other AGNs in the literature. GNz7q is shown as a red star. Comparison samples include $z \sim 2$ quasars (grey points; Lusso et al. 2010), high- z Type 1 faint AGNs, mainly little red dots (blue circles; Maiolino et al. 2025), and luminous quasars at $z \gtrsim 6$ (green triangles; Wang et al. 2021b). The black solid line shows the empirical relationship between k_{bol} and L_{bol} from Duras et al. (2020).

identified by JWST, GNz7q is far more extreme, exhibiting a deviation ~ 1 dex deeper than even this faint population. This profound faintness reinforces the link between GNz7q and the most heavily obscured, rapidly growing BHs in the early Universe

Two physical mechanisms may account for this observed X-ray weakness. First, intrinsic X-ray production may be suppressed by the super-Eddington accretion flow. In this regime, the inner accretion disk becomes geometrically thick (‘slim disk’), which can anisotropically shield the X-ray corona or prevent the formation of a standard reprocessing region due to self-shadowing effects (Madau & Haardt 2024; Inayoshi et al. 2025). Alternatively, the suppression may be extrinsic, resulting from heavy obscuration by a Compton-thick column ($N_{\text{H}} \approx 10^{24} \text{ cm}^{-2}$) that blocks line-of-sight X-rays (Maiolino et al. 2025). Given the source’s high Eddington ratio and its location within a dusty starburst host, it is plausible that a combination of both intrinsic super-Eddington suppression and high column density obscuration contributes to the observed properties.

4.3. Host galaxy properties

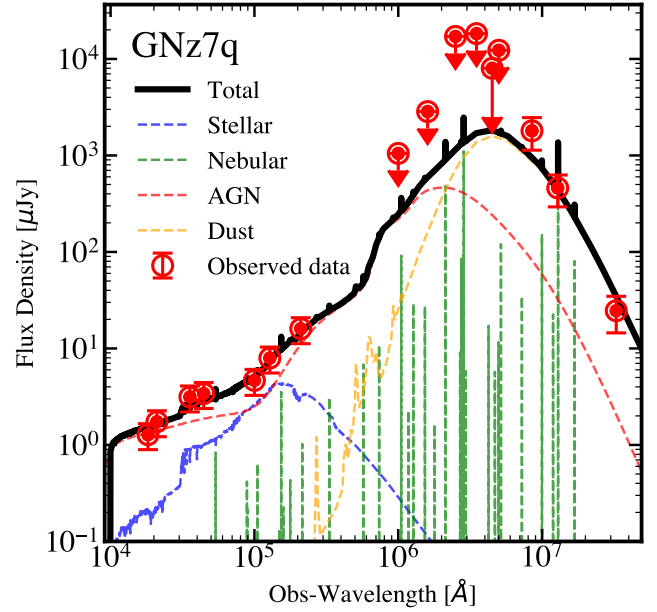

Figure 7. Best-fit multi-component SED decomposition obtained using *cigale*. The observed photometry is shown as red points, comprising both the new JWST observations and archival data (Fujimoto et al. 2022). Dashed lines indicate the individual model components, including stellar population (blue), nebular emission (green), AGN (red), and cold dust (yellow). The solid black line represents the total integrated emission model.

Figure 4 presents the results of our multi-band photometric decomposition using GALFITs. Crucially, the decomposition yields a clear and robust detection of the host galaxy, particularly in the F356W, F444W, F1000W, and F1280W filters where the stellar continuum is prominent. While the host is detected across the full instrument suite (with the exception of the F090W and F115W bands), these rest-frame optical-to-IR bands provide good constraints on the host galaxy emission, allowing the estimation of the host galaxy properties.

Interestingly, the decomposition resolves two components in the rest-frame UV bands, a central component co-located with the quasar, and an off-center component situated approximately 2 kpc away from the mass center determined from the long-wavelength filter. These clumps are similar to features seen in high- z galaxies (e.g., Tadaki et al. 2018; Gillman et al. 2024), suggesting they may represent the star-forming regions in the early Universe. We also obtain a marginal detection in the F2100W filter ($\text{SNR} \approx 2$). At this rest-frame wavelength ($\sim 2.5 \mu\text{m}$), the emission is dominated by the hot dust from the AGN, consistent with the diminishing contribution from the stellar population.

To accommodate both AGN and host galaxy components in GNz7q, we also use the *cigale* for our SED

fitting (Boquien et al. 2019; Yang et al. 2022). In this analysis, we fix the redshift at $z = 7.1899$ and include all the FIR and mm photometry observed with Herschel, SCUBA-2, and NOEMA presented in Fujimoto et al. (2022). For the stellar component, we adopt the single stellar population models of Bruzual & Charlot (2003) (bc03 module), assuming a Chabrier (2003) initial mass function (IMF). The SFH is modeled using a delayed- τ function. We also include a burst component in the model whose SFH can be modeled as an exponential profile. The mass fraction of the late starburst population is allowed to vary between 0 and 0.5 in step of 0.1. Following procedures of Zhuang & Ho (2023) and Tanaka et al. (2025), we set an upper limit on the age of the stellar population, requiring it to be less than 95% of the age of the universe at the galaxy’s redshift ($t_{\text{age}} \leq 0.95 t_{\text{H}}$). We include contributions from ionized gas using the `nebular` module. To account for the potentially extreme interstellar medium (ISM) conditions in high-redshift galaxies, we allow the ionization parameter ($\log U$) to vary between -3 and -1 and the gas-phase metallicity to range from 10% to 100% of the solar value. The dust attenuation is also included in the fitting, following a modified Calzetti et al. (2000) attenuation law (`dustatt_modified_starburst` module). Given the confirmed presence of broad lines in our source, we include an AGN component using the default `skirtor` module in CIGALE (Stalevski et al. 2016; Boquien et al. 2019). We fix the viewing angle to a face-on orientation ($i = 0^\circ$) in the fitting and let AGN emission vary uniformly from 0.1 to 0.9 in the rest-UV-to-optical band (1000Å-10000Å).

In Figure 7, we present our best-fit SED with `cigale` (black), together with the individual components of stellar (blue), nebular (green), AGN (red), and thermal dust emission (yellow) from the stellar component. Our best-fit results suggest that the rest-frame UV-to-optical regime is dominated by the AGN continuum, which is consistent with the independent galaxy+AGN composite SED fitting presented in Fujimoto et al. (2022). In the rest-frame near-infrared (NIR) bands, the stellar emission can be comparable to the AGN emission, which is consistent with our 2D decomposition results. In the rest-frame mid-infrared (MIR) regime, the emission is subsequently dominated by thermal emission from the hot dust torus, which is also consistent with the absence of the residual component in the F1800W map after subtracting the point source component (Figure 4). At the longest wavelengths in the rest-frame far-infrared band, the SED is primarily shaped by the thermal emission originating from cold dust associated with the star-forming activity of the host galaxy. The SED fitting

yields a host stellar mass of $\log(M_*/M_\odot) = 10.5 \pm 0.4$, and a star formation rate of $\text{SFR} = 330 \pm 97 M_\odot \text{ yr}^{-1}$.

We also estimated the SFR using the Paschen- α (Pa α) emission line with the MIRI spectrum. The spectrum was extracted from a circular aperture with a $0''.5$ radius to capture the central emission region. We modeled the emission feature using a single Gaussian profile superimposed on a polynomial continuum (Figure 3). Notably, the line width of the Pa α ($\text{FWHM} = 247 \pm 61 \text{ km s}^{-1}$) is comparable to the [CII] emission line from NOEMA observation ($\text{FWHM} = 280 \pm 40 \text{ km s}^{-1}$, Tab 1, Fujimoto et al. 2022), and indicates that a broad component is not required to describe the observed Pa α line profile, suggesting the emission is dominated by star formation. We measured an integrated Pa α flux of $88 \pm 21 \times 10^{-19} \text{ erg s}^{-1} \text{ cm}^{-2}$, which implies an SFR of $250 \pm 88 M_\odot \text{ yr}^{-1}$. This spectroscopic estimate aligns with the SFR derived from our broadband SED fitting within the uncertainties, confirming that the host galaxy of GNz7q is undergoing vigorous star formation.

However, we note that the current SED fit yields a lower L_{IR} and SFR_{IR} compared to previous estimates ($L_{\text{IR}} = (1.6 \pm 0.3) \times 10^{13} L_\odot$; Fujimoto et al. 2022), possibly due to an underprediction of the SCUBA 850 μm flux (Figure 7). Previous work derived the SFR_{IR} using a modified blackbody fit applied only to the FIR photometry, a method that bypasses the complexities of enforcing energy balance against a quasar-dominated UV/optical continuum. That approach successfully reproduced the 850 μm excess, resulting in a higher inferred L_{IR} . It is worth noting that discrepancies where $\text{SFR}_{\text{IR}} > \text{SFR}_{\text{Pa}\alpha}$ have been observed in high- z dusty galaxies (Álvarez-Márquez et al. 2023; Bik et al. 2024). This excess suggests either that heavy obscuration is attenuating even the Paschen lines, or that we are witnessing a difference in star formation timescales, where Pa α traces instantaneous activity (~ 10 Myr) while the FIR emission integrates heating over a longer period (~ 100 Myr).

4.4. $M_{\text{BH}} - M_*$ relation

The observed tight scaling relations between M_{BH} and host galaxy bulge properties, such as the $M_{\text{BH}} - \sigma$ and $M_{\text{BH}} - M_{\text{bulge}}$ correlations (Magorrian et al. 1998; Ferrarese & Merritt 2000; Gebhardt et al. 2000; Kormendy & Ho 2013), indicate a fundamental co-evolutionary pathway linking these components (Madau & Dickinson 2014). A similar, albeit more dispersed, correlation is also established between M_{BH} and the total stellar mass (M_*) (e.g., Reines & Volonteri 2015). This coupled growth is hypothesized to be particularly critical during the earlier phases of galaxy and BH formation. How-

ever, contrasting with these well-established local benchmarks, AGNs observed at high redshifts ($4.5 < z < 7$) present a significant deviation. These high- z sources systematically populate the region above the extrapolated local $M_{\text{BH}} - M_*$ relationship and are characterized by significant scatters (e.g., Harikane et al. 2023; Maiolino et al. 2024b).

A prevailing explanation for this discrepancy has been observational selection bias, where flux-limited surveys are inherently biased toward detecting only the most luminous and massive BHs whose emission outshines that of their host galaxy (e.g., Shen et al. 2015; Li et al. 2021, 2025a; Tanaka et al. 2025; Silverman et al. 2025). However, recent deep JWST surveys focusing on low-luminosity AGNs at high redshift have argued that this selection effect is insufficient to fully account for the large observed offset, implying a genuine physical difference in the galaxy-BH connection at high redshift (e.g., Pacucci et al. 2023; Maiolino et al. 2024b; Stone et al. 2024).

Based on the derived M_{BH} and M_* , we calculate a mass ratio of $M_{\text{BH}}/M_* = 0.1\%$, and the $M_{\text{BH}} - M_*$ relation for GNz7q as well as other high- z AGNs are shown in Figure 8. Our analysis demonstrates that the derived M_{BH} and M_* values align with the established $M_{\text{BH}} - M_*$ scaling relationship defined in the local Universe (e.g., Kormendy & Ho 2013; Greene et al. 2020). This consistency suggests that some AGN-galaxy systems can achieve a state of co-evolutionary maturity as early as $z \sim 7$ (Silverman et al. 2025; Li et al. 2025a; Onoue et al. 2025).

4.5. Potential Evolutionary Pathway

The suite of derived physical parameters, including M_{BH} and λ_{Edd} , alongside the M_* and SFR, affords crucial constraints on the system’s evolutionary trajectory. When compared with other high- z AGNs, specifically the luminous ground-based quasars and the faint AGNs detected by JWST, this source occupies an intermediate locus in the census of M_{BH} and M_* , i.e., M_{BH} and M_* of GNz7q are greater than those of faint AGNs while smaller than luminous quasars. More importantly, GNz7q is characterized by rapid dual growth in the manner of both BH and host galaxy, driven by high Eddington ratios and substantial star formation activity. This unique feature suggests that GNz7q represents a distinct phase on the BH-galaxy co-evolutionary track.

To investigate the potential evolutionary trajectory of GNz7q, we model the evolution of its M_{BH} and M_* as a function of cosmic time. We investigate the evolutionary tracks of black hole mass using two physically motivated theoretical frameworks and one simplified base-

line. First, we employ the QLF-regulated growth model presented in (Li et al. 2024), which reconstructs BH growth via episodic accretion calibrated against the observed luminosity functions at high redshift. Second, we utilize the semi-analytic DELPHI framework (Dayal et al. 2019). We contrast these realistic scenarios with a simple model assuming continuous accretion at a constant Eddington ratio of unity ($\lambda_{\text{Edd}} = 1$). Regarding the host galaxy assembly, we adopt a simplified assumption of growth via a continuous, constant SFR. While we recognize that reconstructing the full Star Formation History (SFH) offers a more realistic perspective (e.g., Onoue et al. 2025), we opt for the constant SFR approximation to mitigate the substantial uncertainties currently inherent in constraining detailed SFHs at these redshifts. For comparison, we also calculate the corresponding evolutionary paths for other AGN populations, including highly luminous ground-based quasars and faint AGNs, following the methodology detailed in Li et al. (2025b). The M_{BH} and accretion rates are adopted from previous studies (e.g., Kokorev et al. 2023; Furtak et al. 2024; Tripodi et al. 2024; Larson et al. 2023). The SFRs for these high- z AGN host galaxies are determined by combining literature values derived from the rest-UV luminosities with recent average constraints obtained from ALMA observations (e.g., Casey et al. 2025).

Figure 9 presents the modeled evolutionary tracks for GNz7q and the faint AGN comparison sample at $z > 7$. Assuming a realistic SFR and the \dot{M}_{BH} , the modeled evolution for GNz7q demonstrates a potential increase in M_{BH} by approximately 1 dex (with a maximum of ~ 2 dex) and an increase in M_* by ~ 0.5 dex. This modeled growth path converges with the locus of luminous quasars observed in large surveys (e.g., SDSS, HSC) at $z \gtrsim 6$, suggesting that GNz7q is a likely progenitor for these massive systems.

In contrast, we find that the faint AGNs recently discovered by JWST at similar or higher redshifts are challenging to be the direct progenitors of the SDSS-like quasars. For the BH mass, though their large masses make them possible for them to become SMBH at $z \sim 6$ (Larson et al. 2023; Taylor et al. 2025a), the BH mass measurements still have large uncertainties due to distinct models (Inayoshi 2025; Inayoshi & Maiolino 2025; Naidu et al. 2025; Greene et al. 2025). Additionally, the relatively low SFR as well as the barely-detected host galaxies, in particular for LRD, make their host galaxies hardly evolve to the quasar host galaxies, which are usually massive (e.g., $M_* \gtrsim 10^{10} M_{\odot}$ Li et al. 2025b; Ding et al. 2023, 2025; Onoue et al. 2025; Fei et al. 2025a), starbursts (e.g., $\text{SFR} \sim 500\text{--}1000 M_{\odot} \text{ yr}^{-1}$; Wang et al.

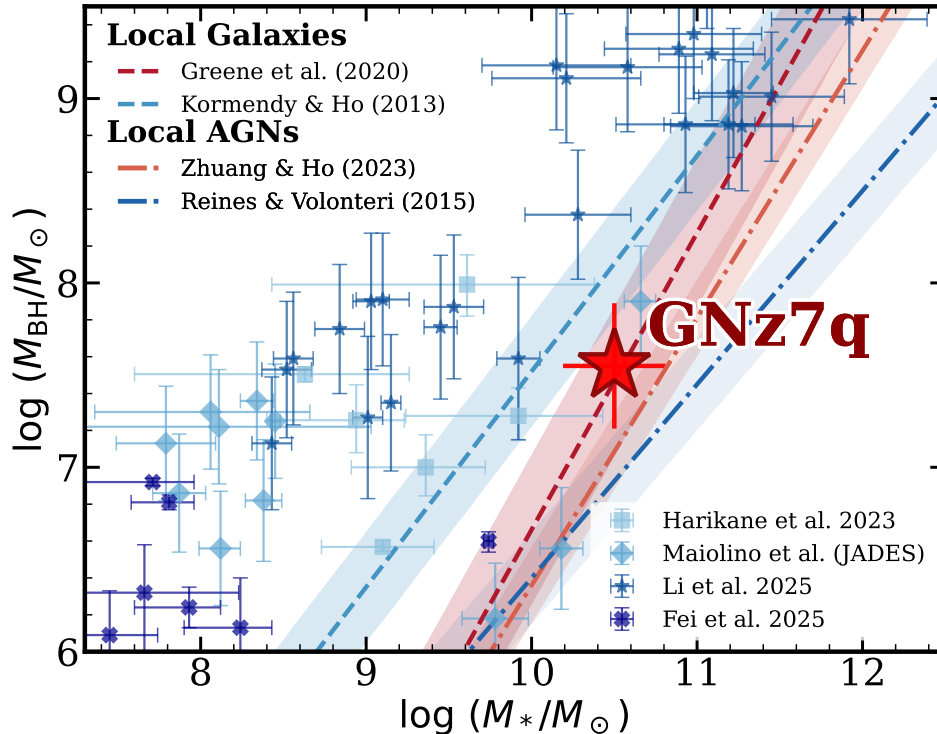

Figure 8. BH mass vs. stellar mass for GNz7q and other high- z AGNs, including the JWST discovered faint AGNs at $z \gtrsim 4$ (Harikane et al. 2023; Maiolino et al. 2024b; Fei et al. 2025a) and luminous quasars at $z \sim 6$ (Fan et al. 2023; Yang et al. 2023; Li et al. 2025b). The dashed and dotted lines represent the empirical relationships for the local galaxies (Kormendy & Ho 2013; Greene et al. 2020) and the local AGNs (Reines & Volonteri 2015; Zhuang & Ho 2023), respectively. GNz7q is shown as the red star.

2013; Decarli et al. 2018; Venemans et al. 2020; Wang et al. 2024b). Indeed, their M_* shows limited growth in a short timescale. This is attributable to the relatively low inferred SFRs, which is further supported by the non-detection of far-infrared dust emission in these targets, particularly those exhibiting red continua (Akins et al. 2025; Casey et al. 2025).

Beyond the comparison of M_{BH} and M_* , the fundamental physical distinctions between GNz7q and the LRDs can be inferred from several other aspects. First, the nature of the obscuration differs significantly. GNz7q exhibits substantial dust reddening consistent with a classic obscured quasar, while LRDs are characterized by a distinct lack of dust (e.g., Naidu et al. 2025). Second, the optical Fe II emission in GNz7q presents as a strong, broad complex, in sharp contrast to the narrow Fe II features typically observed in LRD spectra (e.g., Torralba et al. 2025; D’Eugenio et al. 2025). Finally, we find no evidence in GNz7q for the high column density of neutral gas that is always seen in LRDs (Matthee et al. 2024; Inayoshi & Maiolino 2025), which manifests as significant Balmer breaks or Balmer absorption lines. The absence of these features suggests that GNz7q is distinct from the LRD population. In-

stead, these features reinforce the scenario that GNz7q represents a progenitor to the standard population of luminous blue quasars.

Overall, the derived properties and the modeled evolutionary trajectory of GNz7q position it as a plausible direct progenitor of the luminous quasars so far discovered by ground-based facilities during a decades-long search, while the distinct evolutionary pathway of the faint JWST AGNs suggests they may constitute an intrinsically separate population in the high-redshift universe (Inayoshi & Ho 2025). A key question then is: How could a system like GNz7q have escaped from the “stellar-deficient” earlier stage that may be a legacy of the initial seeding process? This possible bifurcation in early growth trajectories could reflect differences in the large-scale cosmic environment, to be assessed in future work.

5. CONCLUSION

In this work, we presented a comprehensive multi-wavelength characterization of GNz7q, a red quasar at $z = 7.1899$, utilizing the full suite of JWST instrumentation (NIRCam, NIRSpec, and MIRI) and archival data. This analysis provides novel insights into the rapid black

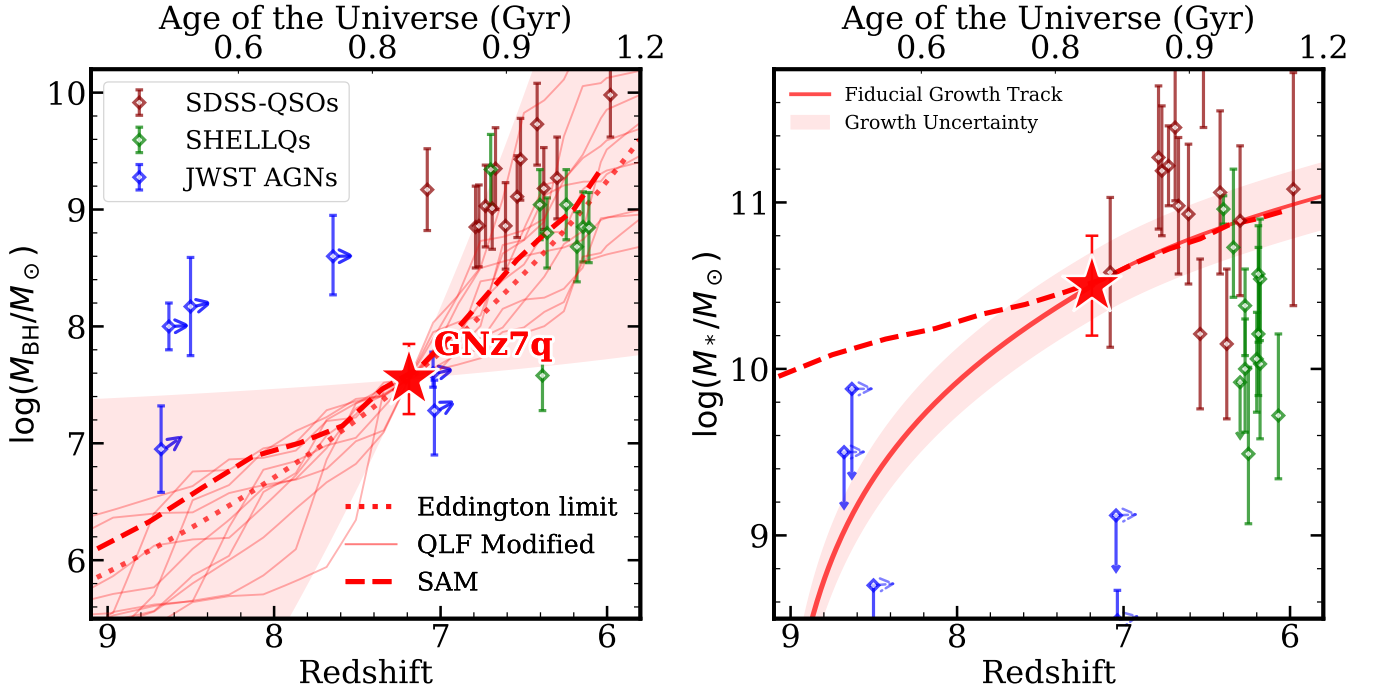

Figure 9. Evolutionary pathways of GNz7q and comparative high- z samples. Left: M_{BH} vs. redshift. The dark-red, green, and blue diamonds denote luminous quasars (Fan et al. 2023), low-luminosity quasars selected from Subaru HSC (e.g., Matsuoka et al. 2018; Onoue et al. 2025) and JWST faint AGNs (e.g., Kokorev et al. 2023; Akins et al. 2025; Furtak et al. 2024; Larson et al. 2023; Taylor et al. 2025b), respectively. Theoretical evolutionary tracks are adopted from Li et al. (2024) (light-red solid line) and the DELPHI semi-analytic model (red dashed line; Dayal et al. 2019). The red dotted line indicates a baseline of assuming continuous Eddington-limited accretion ($\lambda_{\text{Edd}} = 1$), with the red-shaded region denoting the possible region with $0.1 < \lambda_{\text{Edd}} < 2.7$. Right: M_* vs. redshift for our targets and comparison sample. The red shaded region shows the mass growth for GNz7q host galaxy based on the SFH derived from the SED fitting (Table 1), and the red shaded line represents the growth track of M_* from DELPHI semi-analytic model.

hole growth and the co-evolutionary scenario of galaxy-BH systems in the early Universe.

Through a detailed analysis of the NIRSPEC spectroscopy, we derived the following properties for the central AGN:

1. The spectrum exhibits broad Balmer emission lines ($H\alpha$, $H\beta$, $H\gamma$) and strong Fe II lines. Kinematic decomposition of the broad lines reveals a double-Gaussian profile, comprising a narrower ($\text{FWHM} \approx 2200 \text{ km s}^{-1}$), systemic component and a significantly broader ($\text{FWHM} \approx 11000 \text{ km s}^{-1}$), highly redshifted ($\Delta v \approx 3600 \text{ km s}^{-1}$) component.
2. The Balmer decrement of the narrow emission lines ($H\alpha/H\beta$ ratio) and the continuum SED slope suggest a relatively low level of dust attenuation within the broad-line region. Assuming a standard extinction law, we derive an extinction of $A_V = 0.21^{+0.08}_{-0.09}$.
3. Applying local virial scaling relations yields a BH mass of $\log(M_{\text{BH}}/M_\odot) = 7.55 \pm 0.34$ and a super-Eddington accretion ratio of $\lambda_{\text{Edd}} = 2.7 \pm 0.4$.

These properties identify GNz7q as a rapidly growing massive BH in the Epoch of Reionization, exhibiting one of the highest known accretion rates at this redshift.

4. This high Eddington accretion rate is further supported by the detection of the broad neutral [O I] emission line, which has been observed in several high- z faint AGNs discovered by JWST.
5. The observed X-ray bolometric correction (k_{bol}) presents a significant deviation ($> 5\sigma$) from the empirical relations, implying a suppression of the X-ray emission in GNz7q. This depression is likely attributable to the intrinsic effects of a high accretion rate, heavy obscuration by high column density material along the line of sight, or the interplay of both mechanisms.

Utilizing NIRCcam and MIRI imaging alongside MIRI spectroscopy, the host galaxy of this system is characterized as:

5. Morphological decomposition robustly resolves the host galaxy’s stellar continuum in the rest-frame

optical and near-infrared bands, revealing an effective radius of $R_e = 1.01$ kpc and a Sérsic index of $n = 1.9$. In the rest-frame mid-infrared, the stellar contribution declines, indicating the transition to a regime dominated by thermal emission from the AGN dust torus. Interestingly, high-resolution rest-frame UV imaging reveals a clumpy morphology characterized by two distinct structures.

6. The SED fitting yields a decomposition consistent with standard system components. The rest-frame UV is driven by the AGN, while the host stellar emission becomes important in the rest-optical/NIR band. At mid-IR band, the SED is dominated by the hot torus emission. The thermal emission from the dust in the host galaxy dominates the far-IR and sub-mm emission.
7. The far-infrared SED implies a vigorous star formation rate of $\text{SFR}_{\text{FIR}} = 330 \pm 97 M_{\odot} \text{ yr}^{-1}$, confirming the host as a dusty starburst. This value is consistent, within uncertainties, with the independent estimate derived from the Pa α emission line ($\text{SFR}_{\text{Pa}\alpha} = 250 \pm 88 M_{\odot} \text{ yr}^{-1}$).
8. The SED fitting yields a substantial dust attenuation for the host galaxy ($A_{V,\text{host}} = 3.1 \pm 0.8$). This value significantly exceeds the attenuation derived for the central AGN component, pointing to distinct dust distributions obscuring the host galaxy and the central engine, respectively.

The derived properties of the BH and host galaxy position GNz7q in a unique phase of the BH-galaxy co-evolution scenario:

9. In contrast to many JWST-identified faint AGNs and high- z quasars discovered from all-sky surveys that appear over-massive relative to their hosts, GNz7q exhibits a mass ratio of $M_{\text{BH}}/M_* \approx 0.1\%$, placing it consistently on the local $M_{\text{BH}} - M_*$ scaling relation. This alignment indicates that the BH-galaxy relation can be achieved as early as $z = 7.1899$.
10. In conclusion, GNz7q offers a rare glimpse into the progenitor phase of luminous quasars, illustrating a distinct stage of early co-evolution before the onset of the unobscured, SDSS-like quasar regime.

The modeled evolutionary trajectory of GNz7q identifies it as a dust-obscured, super-Eddington progenitor

likely representing an early assembly phase of luminous $z \sim 6$ quasars. Consequently, we anticipate that future deep surveys targeting higher redshifts ($z \gtrsim 8 - 10$) will unveil a population of progenitor systems that mirror the properties of GNz7q. Crucially, our growth models suggest these earlier sources will not exhibit the extreme ‘overmassive’ BH mass ratios seen in most faint AGN populations; instead, they should populate the extension of the local $M_{\text{BH}} - M_*$ scaling relation. This prediction implies that the physical coupling between BH accretion and host galaxy assembly is likely established within the first few hundred million years of the Universe.

Facility: JWST, NOEMA

ACKNOWLEDGEMENTS

We are grateful to Jinyi Yang and Feige Wang for their insightful discussions about the broad line fitting. We are grateful to Zhiwei Pan and Yuming Fu for their discussions about the BH mass estimator.

APPENDIX

A. EVALUATION OF ADDITIONAL SPECTRAL COMPONENTS

The inherent complexity and multi-component nature of quasar spectra can make the fitting results highly dependent on the adopted model. We therefore performed a model comparison, evaluating a suite of models with different combinations of components and parameter constraints. To identify the optimal description, we employed the Bayesian Information Criterion (BIC):

$$\text{BIC} \equiv \chi^2 + k \ln n, \quad (\text{A1})$$

where k is the number of free parameters and n is the number of data points. The model that yielded the minimum BIC value, representing the best compromise between goodness-of-fit (χ^2) and model simplicity (penalized by k), was adopted as our final best-fit.

We firstly performed a model comparison to determine the optimal number of Gaussian components required to characterize the broad Balmer lines. A simple, single-component model is strongly disfavored, yielding a $2,000 \text{ km s}^{-1}$ redshift relative to the systemic velocity and a significantly poorer fit ($\Delta\text{BIC} = 116$) compared to the model in Section 3.1 (Figure A.1). Conversely, models incorporating three or more components provided no statistically significant improvement. We thus conclude that our two-component model provides the most parsimonious and statistically robust description of this source’s broad line region. This redshifted broad $\text{H}\beta$ component has been observed in other sources at different redshifts, in particular for sources with high Eddington accretion rates (Marziani et al. 2009), whose origin is still under debate, while all potential explanations regard it as a non-virial component within the BLR. Therefore, we estimate the BH and AGN properties only using the nBLR.

We also consider the possibility that the Iron emission lines have the same broadening and shifting compared to the $\text{H}\beta$ emission line (Sulentic et al. 2012). In this consideration, we fixed the line width of the Fe II lines to that of the broad $\text{H}\beta$ component (the extremely broad component is not included). However, it failed to reproduce prominent features in the Iron pseudo-continuum, particularly the emission spikes in the rest-frame 5100–5500 Å. More importantly, this model is disfavored by a significantly larger BIC ($\Delta\text{BIC} = 110$). Therefore, we conclude that the iron-emitting region is kinematically decoupled from the broad line region in this source. Our best-fit model, which allowed the Fe II width to be a free parameter, converged on a significantly narrower

Figure A.1. Spectral fit of the $\text{H}\beta$ + $[\text{O III}]$ complex adopting a single-component model for the broad emission line. The continuum subtracted spectrum is shown as black solid line, and the best-fit model is shown as red thick line. The narrow line model and the broad line model are shown as a green line and a blue dashed line, respectively.

profile, with $\text{FWHM}_{\text{Fe}}/\text{FWHM}_{\text{H}\beta} \approx 46\%$. This model comparison confirms that our fiducial setup (Section 3.1) is preferred.

B. MIRI LRS SPECTRUM

Figure B.1 illustrates the two-dimensional and extracted one-dimensional MIRI LRS spectra, accompanied by the best-fit model and corresponding residuals. Due to the limited spectral resolution inherent to the MIRI LRS instrument, the line widths for the Near-Infrared (NIR) features were not constrained in this analysis.

Figure A.2. Comparison of different kinematic models for Iron. The observed spectrum is shown in black for the rest-frame 4400–4950 Å and 5050–5500 Å regions. The blue line indicates the Iron pseudo-continuum with the line width constrained to match the broad H β profile, while the red line represents our fiducial model.

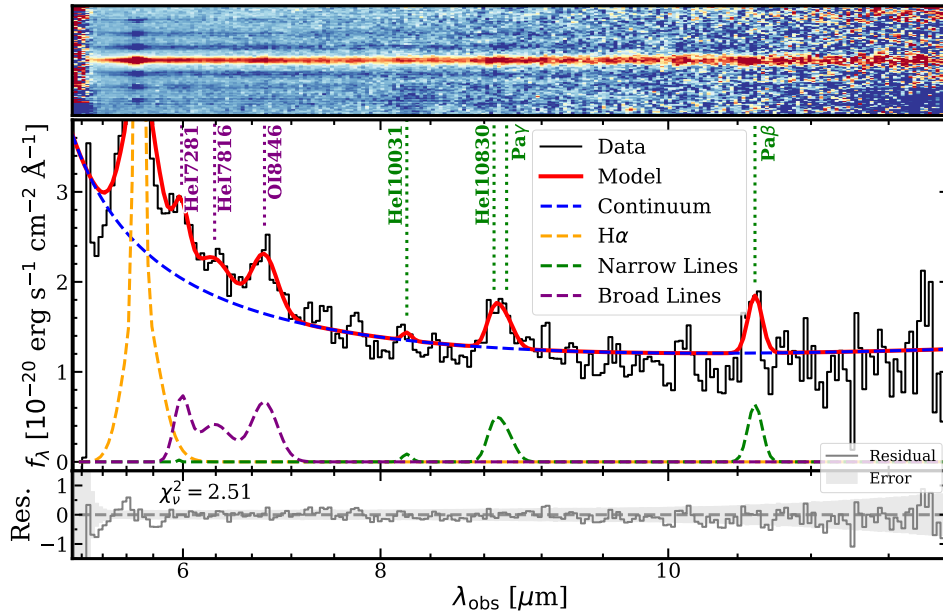

Figure B.1. The observed rest-frame optical-to-NIR spectrum, generated from the MIRI LRS observation. *Top:* 2D spectrum from the MIRI LRS observation. *Middle:* 1D spectrum extracted from the 2D spectrum and the corresponding model. Black and red solid lines represent the observed spectrum and the resultant best-fit model, respectively. Component modeling includes a power-law continuum (blue dashed line), H α emission (orange dashed line), and decoupled narrow (green) and broad (purple) emission line profiles. The corresponding emission lines are labeled with different colors (purple for broad lines and green for narrow lines). Note that we do not consider the instrumental broadening during the fitting, the broadening of those rest-frame NIR lines can be caused by the instrument. *Bottom:* The residual between the data and the model. The 1σ error is shown as the gray shaded region.
